The tricuspid annulus lies anterior to the body of the RA, and its inferior portion lies a short distance (approximately 1 to 4 cm) anterior to the eustachian ridge, although its course varies among individuals. The CTI is the part of the RA between the ostium of the IVC and the eustachian ridge (posteriorly) and the tricuspid annulus (anteriorly). The CTI runs in an anterolateral-to-posteromedial direction, from the low anterior RA to the low septal RA. The CTI belongs to the trabeculated part of the RA, and its surface is very rough. Its width and muscle thickness are variable, from a few millimeters to more than 3 cm in width and more than 1 cm in depth. The CTI becomes wider in a medial-to-lateral direction, and it is thinnest in its central portion. A thick eustachian ridge (greater than 4 mm) is seen in 24% of patients. The eustachian ridge (often composed of partly or largely fibrous tissue) occurs as an elevation on the CTI. The area between the tricuspid annulus and the eustachian ridge is referred to as the sub-eustachian isthmus, whereas the downslope of the eustachian ridge leads to the junction of the RA and IVC. The pectinate muscles fan out from the crista terminalis and encroach upon the CTI for variable distances, but typically spare the myocardium just atrial to the tricuspid valve. This smooth portion of the CTI is referred to as the vestibular portion. The pectinate muscles are more prominent on the lateral side of the CTI, but become progressively thinner as they ramify branches toward the CS os. In the normal heart, CTI anatomy can be flat, “hilly” (from prominent eustachian ridge and pectinate muscles), concave, or have a pouch-like recess.^{5,6} Occasionally there is a depression (sub-eustachian pouch or sinus of Keith) on the CTI just lateral to the CS os, which can be very deep.^{4,7}

Typical Atrial Flutter Circuit

Typical AFL is the most common type of macroreentrant AT. The macroreentrant circuit is defined by anatomical barriers including the tricuspid annulus, crista terminalis, IVC orifice, eustachian ridge, CS os, and probably the fossa ovalis. However, the lines of conduction block necessary to provide adequate path length for the flutter reentry circuit can be functional or anatomical. The anterior boundary of the tachycardia circuit has been well established as being the tricuspid ring. The posterior boundaries, however, are more complex and not as well-defined. The posterior borders occur at a variable distance from the anterior border, narrowest in the region of the eustachian ridge (CTI) and widest in the anterior part of the RA.^{4,7,8}

The CTI provides the protected zone of relatively slow conduction necessary for the flutter reentry circuit. The area of slowest conduction is probably localized in the lateral aspect of the CTI in younger patients and in the medial aspect in older patients.⁹ Conduction velocity in the CTI during pacing in sinus rhythm is slower in patients with typical

AFL compared with those without any history of AFL.⁵ The mechanism of the slower conduction velocity in the CTI, relative to the interatrial septum and RA free wall, is uncertain but can be related to the anisotropic fiber orientation. With aging or atrial dilation, intercellular fibrosis can change the density of gap junctions and produce nonuniform anisotropic conduction through the trabeculations of the CTI.^{7,10}

Key to the development of typical AFL is the formation of a line of block in the region between the SVC and IVC in the RA free wall. This line of block acts as a critical lateral boundary that prevents short-circuiting of the flutter wavefront, whereby the reentrant wave catches the “tail of refractoriness” and hence extinguishes. This line of block is usually functional, but may be fixed. The creation of a line of block between the vena cavae or anterior in the RA free wall permits induction of AFL in otherwise normal atria. This explains the observation that AFL most often does not start immediately after a premature atrial complex (PAC) or burst rapid atrial pacing; rather its onset is usually preceded by a transitional rhythm (atrial fibrillation [AF]) of variable duration, which helps induce the functional line of block between the venae cavae. When a fixed (i.e., anatomic) intercaval line of block exists (e.g., atriotomy scar following surgical repair of congenital heart disease), antecedent AF may not be necessary to produce AFL.¹¹

The crista terminalis plays an important role as a functional barrier during typical AFL. Conduction delay and rate-related transverse block across the crista terminalis has been consistently observed in sinus rhythm and during pacing. During typical AFL, a line of transverse conduction block along the crista terminalis serving as a lateral boundary can be determined by the presence of double and split potentials recorded. Structural characteristics of the crista terminalis influence transverse conduction; steep slope and arborization of the crista terminalis have been implicated as geometric factors in its transverse conduction block. Typical AFL is more likely to occur in the setting of a thicker and continuous crista terminalis, and these patients are more likely to exhibit transverse crista terminalis conduction block at longer pacing cycle lengths (PCLs), as opposed to controls. Similarly, the region posterior to the crista terminalis (the posterior smooth-walled RA) also has been shown to demonstrate functional transverse conduction block during AFL or rapid pacing.^{10,12}

The width of the activation wavefront in typical AFL varies considerably, and is determined by the distance between the anterior and posterior boundaries at any given part of the circuit. It is very narrow inferiorly at the CTI and substantially wider moving upward. Substantial variability in the upper part of the circuit is a result of the large distance between anterior and posterior borders and anatomical barriers superiorly, combined with variability in the completeness of the posterior border. Recent studies suggest that the posterior block line is located along the posteromedial RA wall, posterior to the crista terminalis. Despite a relatively similar activation sequence, the active circuit (as determined by entrainment mapping) is variable. Most commonly, the reentrant wavefront courses not around the tricuspid annulus but obliquely between anterior and posterior borders away from the tricuspid annulus along any available, more rapidly conducting segments. Consequently, significant portions of the RA, including areas around the tricuspid annulus, can often be passively activated. In many subjects, the upper portions of the circuit pass behind the RA appendage and lie near or at the posterior circuit border, or they bifurcate around the SVC or RA appendage. The posterior border can extend completely or partially between the IVC and the SVC.^{8,13,14}

Typical AFL is of two types: counterclockwise and clockwise. In counterclockwise AFL (“counterclockwise” as viewed in the left anterior oblique [LAO] view from the ventricular side of the tricuspid annulus), the activation wavefront propagates caudocephalically up the septal side of the tricuspid annulus toward the crista terminalis and advances

cephalocaudally down the lateral wall of the RA to reach the lateral tricuspid annulus, after which it propagates through the CTI. In clockwise AFL (also known as “reverse typical” AFL), activation propagates in the direction opposite to that in counterclockwise typical AFL (Fig. 12.1). In both types of typical AFL, the flutter circuit is entirely confined within the RA. Left atrium (LA) activation occurs as a bystander and follows transseptal conduction across the inferior CS-LA connection, Bachmann’s bundle, and/or fossa ovalis.

Counterclockwise AFL is the most common form of typical AFL. Clockwise AFL is observed in only 10% of clinical cases, despite the fact that it is easily inducible with programmed electrical stimulation. Clockwise AFL can be induced in the electrophysiology (EP) laboratory in approximately 50% of patients who clinically present with only counterclockwise AFL. The 9:1 clinical predominance of counterclockwise AFL can be related to the localization of an area with a low safety factor for conduction in the CTI, close to the atrial septum. In addition, counterclockwise AFL is more likely to be induced with rapid atrial pacing from the CS os. Conversely, clockwise AFL is more likely to be induced with pacing from the low lateral RA pacing. These observations may be related to the anisotropic properties of the CTI and the devel-

opment of rate-dependent conduction delays and unidirectional block necessary for tachycardia induction, which may be affected by the site of stimulation.

Interrelationship of Atrial Flutter and Atrial Fibrillation

Although AF and typical AFL frequently coexist, the pathophysiological interrelationship between the two arrhythmias is still uncertain. Clinical AFL occurs in more than one-third of patients with AF. AF often precedes the onset of AFL and can also develop after the successful catheter ablation of AFL. Similar predisposing factors are found in both arrhythmias, including age, hypertension, heart failure, sleep apnea, and chronic pulmonary disease. It is likely that the atrial electrical and structural remodeling that underlies or is induced by AF can also promote the occurrence of AFL, or vice versa. Evidence also suggests that AF plays an important role in the genesis of typical AFL. It is also possible that at least some episodes of AFL can degenerate into AF (Fig. 12.2). AFL with sufficiently short cycle lengths (CLs) can result in fibrillatory conduction, which manifests as clinical AF.^{11,15,16}

Multiple studies have shown that, in the vast majority of instances of induced or spontaneous AFL, antecedent AF is necessary for the

Fig. 12.1 Endocardial Activation During Atrial Flutter (AFL). Counterclockwise (upper panel) and clockwise (lower panel) typical AFL are recorded in the same patient. Catheter position and wavefront activation during the tachycardia are illustrated in a left anterior oblique fluoroscopic view (right side). The ablation catheter (Abl) is positioned at the cavotricuspid isthmus, and the Halo catheter is positioned around the tricuspid annulus, with the distal end at the lateral aspect of the cavotricuspid isthmus. CS, Coronary sinus; CS_{dist}, distal coronary sinus; CS_{prox}, proximal coronary sinus; TA_{dist}, distal tricuspid annulus; TA_{prox}, proximal tricuspid annulus.

Fig. 12.2 Typical Atrial Flutter (AFL) Degenerating Into Atrial Fibrillation (AF). Surface electrocardiogram and intracardiac recordings are shown during typical counterclockwise AFL that spontaneously converts into AF. Note the faster ventricular response during AFL (with 2:1 atrioventricular conduction) as compared with that during AF because of the slower and more regular atrial rate (as recorded in the coronary sinus and around the tricuspid annulus) during AFL as compared with that during AF. CS_{dist} , Distal coronary sinus; CS_{prox} , proximal coronary sinus; TA_{dist} , distal tricuspid annulus; TA_{prox} , proximal tricuspid annulus.

development of AFL (Fig. 12.3). This is because it is during the AF that a critical lateral boundary (i.e., a functional line of block) necessary for the development of AFL forms between the SVC and IVC. Hence, without preceding AF, it is difficult to initiate AFL.¹⁷ Thus it is not surprising that recent studies have implicated pulmonary vein (PV) triggers in the initiation of typical AFL. The PV triggers induce a transitional period of AF, which then organizes to AFL once the functional line of block critical for the flutter circuit is formed. If this functional boundary does not develop, AF will either persist or spontaneously convert back to sinus rhythm. Not infrequently, the use of antiarrhythmic drug therapy (especially class IC agents) facilitates the conversion of AF to AFL, presumably by changing the atrial substrate to favor development of the intercaval line of block that could not form previously without drug effects.¹⁷

Among patients who initially present with isolated typical AFL, the incidence of AF is very high, around 25 times higher than in the general population, even after the elimination of AFL with catheter ablation. Following AFL ablation, AF can develop in up to 82% of these patients.¹⁸ Hence it appears that AFL is often an early marker of atrial electrical disease that frequently progresses to AF. Eradication of the flutter circuit alone by CTI ablation is not expected to eliminate AF that likely was the underlying trigger for AFL in most patients. After CTI ablation, the atria still are susceptible to PV triggers, which continue to induce AF episodes. After successful ablation of AFL, AF wavefronts can no longer “reorganize” into typical AFL because the CTI (the target for AFL ablation) is no longer available as a critical component of an AFL reentrant circuit, at which time AF either persists or terminates. Frequently, however, AF simply becomes clinically manifest. In fact, it is likely that AF already exists in many patients with supposed “isolated” AFL, but has not been clinically documented because of the preferential organization of AF wavefronts into AFL. Intensified continuous cardiac monitoring fre-

quently confirms the additional existence of AF in many patients with suspected isolated AFL.¹⁹

On the other hand, in patients presenting with both AF and AFL, the successful elimination of AF was found to prevent the recurrence of both AF and AFL. PV isolation alone was equally as effective as the combined ablation strategy (PV isolation plus CTI ablation), and more effective than CTI ablation alone in providing long-term freedom from both arrhythmias.²⁰ Even in patients presenting with isolated AFL and no prior history of AF, PV isolation (without CTI ablation) could prevent the recurrence of AFL.²¹

In summary, data suggest that bursts of AF may serve as the primary electrical disorder in patients with typical AFL. These bursts induce a more stable macroreentrant arrhythmia (typical AFL) in susceptible individuals. After eradication of the flutter substrate by CTI ablation, the same PV triggers manifest as AF. PV isolation can potentially control both arrhythmias in patients with AFL, and those with coexistent AFL and AF.^{15,18,22}

Double-Wave Reentry

A typical AFL circuit with a large excitable gap may allow a second excitation wave to be introduced into the flutter circuit by a critically timed atrial extrastimulus (AES), so that two wavefronts occupy the same circuit simultaneously. This type of AFL is designated “double-wave reentry.”

Double-wave reentry is manifest by acceleration of the tachycardia rate, but with identical surface ECG morphology and intracardiac activation sequence. It can be recognized by the simultaneous activation of the superior and inferior regions of the tricuspid annulus, with all activation being sequential. This rhythm rarely lasts for more than a few beats and can serve as a trigger for AF. Because the CTI is still a necessary part of the circuit, double-wave reentry is amenable to CTI ablation.

Fig. 12.3 Atrial Fibrillation (AF) Degenerating Into Typical Atrial Flutter (AFL). Surface electrocardiogram (ECG) and intracardiac recordings shown normal sinus rhythm (NSR, at left) followed by an early-coupled premature atrial ectopic beat that induces AF (as evident by the disorganized atrial activity on the surface ECG as well as in the coronary sinus and around the tricuspid annulus), which shortly afterwards converts spontaneously into typical counterclockwise AFL. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; TA_{dist}, distal tricuspid annulus; TA_{prox}, proximal tricuspid annulus.

EPIDEMIOLOGY AND NATURAL HISTORY

It is estimated that the overall incidence of AFL in the United States is 88 per 100,000 person-years. The prevalence of AFL increases with age to almost 600 per 100,000 among those older than 80 years. AFL accounts for approximately 15% of supraventricular arrhythmias. Although in clinical practice AFL appears to be less common than paroxysmal supraventricular tachycardia, population-based data show that in the general population, AFL is diagnosed for the first time more than twice as often. Adjusted for age, the incidence of AFL in men is 2 to 3 times that in women.

Paroxysmal AFL can occur in patients with no apparent structural heart disease, whereas chronic AFL is usually associated with underlying heart disease, such as valvular or ischemic heart disease or cardiomyopathy. At highest risk of developing AFL are men, older adults, and individuals with preexisting heart failure or chronic obstructive lung disease. In approximately 60% of patients, AFL occurs as part of an acute disease process, such as acute pericarditis, acute exacerbation of chronic pulmonary disease, acute pneumonia, thyrotoxicosis, alcoholism, following cardiac or pulmonary surgery, or during acute myocardial infarction (MI).

The natural history of typical AFL is often interlinked with AF. Typical AFL and AF frequently coexist. The majority (75%) of patients with AFL also have documented AF at the time of presentation. Successful CTI ablation to cure AFL does not seem to improve the natural history of progression to AF, even in patients with AFL as the only

clinical arrhythmia. Up to 82% of these patients develop AF; the majority of those develop AF in the first year after ablation of AFL.^{15,18,22}

CLINICAL PRESENTATION

Patients with AFL can be completely asymptomatic, or they may present with a spectrum of symptoms ranging from palpitations, lightheadedness, fatigue, reduced activity tolerance, or dyspnea, to acute pulmonary edema or acute coronary syndrome in susceptible patients.

The clinical manifestations of AFL strongly depend on the ventricular rate during the AFL, the presence of structural heart disease, and the underlying functional status. Fast ventricular rates and the loss of effective atrial contraction have significant hemodynamic consequences, especially in patients with systolic or diastolic heart failure. Furthermore, AFL with a chronically rapid heart rate can lead to tachycardia-mediated cardiomyopathy and heart failure. In fact, some patients remain asymptomatic until they present with a thromboembolic event or with decompensated heart failure secondary to tachycardia-induced cardiomyopathy. AFL occurs in approximately 25% to 35% of patients with AF, in which case AFL may be associated with worsening of the intensity of symptoms because of more rapid ventricular rates.

INITIAL EVALUATION

Clinical symptoms are not usually helpful in distinguishing typical AFL from other atrial tachyarrhythmias. Documentation of the arrhythmia

during spontaneous symptoms on ECG, ambulatory cardiac monitoring, or cardiac implantable electronic devices (loop recorders, pacemakers, defibrillators) is important to establish the diagnosis. The 12-lead ECG diagnosis of typical AFL is frequently accurate, but it can occasionally be misleading (see later).

Initial assessment includes the determination of cardiopulmonary stability, symptom onset and severity, thromboembolic versus hemorrhagic risk, and potential substrates or triggers of AFL. An echocardiogram is necessary to evaluate for structural heart disease. Evaluation for ischemic heart disease is considered in patients with angina, heart failure, or high risk for coronary artery disease. Additional laboratory evaluation typically includes the assessment of serum electrolytes, blood counts, renal and hepatic function, as well as thyroid function.

PRINCIPLES OF MANAGEMENT

Management of AFL should be aimed at identifying and treating underlying causes of the arrhythmia, as well as reducing symptoms, improving quality of life, and preventing cardiovascular morbidity and mortality associated with AFL. In addition, unlike AF, curing AFL is an attainable treatment goal.

There are four main issues that must be addressed in the treatment of AFL: (1) ventricular rate control, (2) restoration of normal sinus rhythm (NSR), (3) maintenance of NSR, and (4) prevention of systemic embolization (Figs. 12.4 and 12.5).²³

Rate Control

Ventricular rate control during AFL is important to prevent hemodynamic instability, improve symptoms and functional capacity, and prevent tachycardia-mediated cardiomyopathy. Oral or intravenous (IV) AVN blockers are utilized for rate control, depending on the severity of symp-

toms and the degree of hemodynamic compromise caused by the tachycardia. Notably, the ventricular rate can be very difficult to control in typical AF, more so than during AFL, because of the slower and more regular atrial rate (see Fig. 12.2). As a consequence, controlling clinical symptoms frequently requires cardioversion.²⁴

Beta-blockers or nondihydropyridine calcium-channel blockers (verapamil and diltiazem) are the drugs of choice for rate control, and appear to have equivalent efficacy. Care should be used in administering these medications in patients with acutely decompensated heart failure. Beta-blockers are preferred in patients with cardiomyopathy, ischemic heart disease, and following surgical procedures. Verapamil and diltiazem are preferred in patients with reactive airway disease.²³

Digoxin is less effective and requires a longer time to achieve rate control, but may be considered if beta-blockers and calcium channel blockers have failed or have intolerable side effects. Digoxin reduces the resting heart rate, but it is seldom effective in ambulatory patients because its effects are mediated by the enhancement of vagal tone, which is offset during exertion. Thus digoxin has traditionally been used as a second-line agent, usually in sedentary patients or those with heart failure or hypotension. Recently, however, several systematic reviews and meta-analyses found that digoxin use was associated with a greater risk for mortality in patients with AF, regardless of concomitant heart failure. Some studies have suggested that AF nullifies the effect of digoxin in reducing hospitalizations for heart failure patients. Hence the long-term use of digoxin has been discouraged.^{24–28}

Amiodarone may be considered for rate control when other AVN blockers are unsuccessful or not tolerated. IV amiodarone is useful for acute control of the ventricular rate, and can be of particular value in acutely ill patients or those with acutely decompensated heart failure or severe hemodynamic compromise. Because of the possibility of termination of AFL by amiodarone, though very small, pericardioversion anticoagulation strategies (as discussed later) should be considered,

depending on the individual patient's risk/benefit profile. Given its potential toxicity, amiodarone is not recommended for long-term rate control.²³

In patients with AFL and ventricular preexcitation causing rapid ventricular response, prompt direct-current cardioversion is recommended, especially when hemodynamic compromise is present. IV procainamide or ibutilide to restore NSR or to slow the ventricular rate may be considered in hemodynamically stable patients. Importantly, drugs that preferentially slow AVN conduction without prolonging bypass tract refractoriness (such as verapamil, diltiazem, adenosine, oral or IV digoxin, and IV amiodarone) can accelerate the ventricular rate and potentially precipitate hemodynamic collapse and ventricular fibrillation (VF) in high-risk patients with Wolff-Parkinson-White syndrome. Unlike the IV route of administration, chronic oral amiodarone therapy can slow or block bypass tract (BT) conduction. Limited data exist regarding the use of beta-blockers; nonetheless, these drugs theoretically pose a similar potential risk in this situation, and they should be used with caution.²⁹

Restoration of Sinus Rhythm

Restoration and maintenance of NSR in patients with AFL is preferred to rate control strategy. The elimination of AFL is associated with relief of symptoms, improved functional status and quality of life, reduced risk of systemic thromboembolism, and prevention of tachycardia-induced cardiomyopathy. In addition, reduction in atrial remodeling can potentially help reduce the future risk of AF. Therefore rate control strategy is reserved to patients with contraindication to anticoagulation, those with intraatrial thrombi, or patients with very poor functional status and multiple comorbidities when the risks associated with rhythm control strategy outweigh the benefits.²³

Several options are available for termination of AFL, including external direct-current therapy, antiarrhythmic drugs, overdrive atrial pacing, and catheter ablation. The timing of attempted cardioversion is influenced by the duration of AFL, the severity of the patient's symptoms, the adequacy of rate control, and the risk of thromboembolism. Prompt cardioversion is recommended for patients with rapid ventricular rates and hemodynamic compromise attributed to AFL (hypotension, acute heart failure, myocardial ischemia) or ventricular preexcitation. Cardioversion is also considered to restore NSR in stable but symptomatic patients with persistent AFL, especially when ventricular rate control remains suboptimal. For stable patients with adequate heart rate control and minimal symptoms, conversion to sinus rhythm may be deferred until catheter ablation, if performed in a timely manner.

Peri-Cardioversion Anticoagulation

In spite of the organized atrial rhythm and apparent preserved atrial contraction during AFL, the thromboembolic risk is practically no different for this rhythm than for AF. In stable patients with AFL of a duration longer than 48 hours or of unknown duration, any mode of cardioversion (electrical, chemical, pacing, or ablation) should be delayed until the patient has been anticoagulated at appropriate levels for 3 to 4 weeks or transesophageal echocardiography (TEE) has excluded atrial thrombi. TEE may also be considered in patients with high thrombotic risk (e.g., severe valvular or congenital heart disease, prior thromboembolic events, severe cardiomyopathy), even when the duration of AFL is less than 48 hours.²³

If urgency of cardioversion (because of severe symptoms or hemodynamic instability) precludes TEE, therapeutic doses of low-molecular-weight heparin or unfractionated heparin should be administered as soon as possible, concurrent with or, preferably, prior to cardioversion.

Electrical Cardioversion

External direct-current cardioversion of AFL is successful in more than 95% and is typically achieved with relatively lower levels of energy (i.e., 5 to 50 joules) as compared with AF. In general, electrical cardioversion is preferred to chemical cardioversion, given the higher efficacy and the lower low risk of proarrhythmia; however, it requires sedation or anesthesia, and is contraindicated in patients with digitalis toxicity or those with hypokalemia.²³

Overdrive Atrial Pacing

Overdrive atrial pacing can terminate AFL in about 82% (range 55% to 100%), and is especially effective in patients receiving antiarrhythmic medications. Overdrive pacing is particularly useful in patients with preexisting atrial pacing wires (as part of a permanent pacemaker or defibrillator, or temporary epicardial pacing wires following cardiac surgery). In these patients, overdrive atrial pacing may be preferred to electrical cardioversion since it obviates the need for sedation. Insertion of a temporary pacing wire for overdrive pace termination of AFL may be considered when electrical cardioversion is contraindicated (e.g., in the setting of digitalis toxicity) or when sedation is not feasible. Trans-esophageal atrial pacing, on the other hand, is rarely utilized, since it requires sedation and esophageal intubation, and is much less effective than electrical cardioversion.²³

Overdrive atrial pacing is started at a rate 5% to 10% faster than the flutter atrial rate and is maintained for 15 or more seconds. Overdrive pacing is repeated at incrementally faster rates until NSR is restored as AF develops. When overdrive atrial pacing alone fails, high-frequency (50-Hz) burst atrial pacing or overdrive pacing with atrial extrastimuli can be effective. One potential drawback to atrial pacing is the potential conversion of AFL to AF; even then, induction of AF can be associated with better ventricular rate control and less symptom, and may subsequently revert spontaneously to NSR.²³

Pharmacological Cardioversion

Pharmacological cardioversion of AFL is generally less effective than electrical cardioversion and carries the potential risk of proarrhythmia, but can be an option when sedation is not available or not well tolerated or when indicated by patient preference.

Ibutilide and dofetilide are the most effective agents for pharmacological conversion of AFL. Other antiarrhythmic agents, including sotalol, amiodarone, class IA (e.g., procainamide), or class IC agents (e.g., flecainide, propafenone), have limited efficacy. AVN blockers (beta-blockers, digoxin, and calcium-channel blockers) are generally not effective for restoration of NSR.²³

IV ibutilide is the drug of choice for chemical cardioversion; it can terminate AFL (usually within 30 minutes) in 38% to 76% of cases, regardless of the duration of the arrhythmia. The efficacy of ibutilide is significantly higher than that of IV procainamide (76% vs. 14%), IV sotalol (70% vs. 19%), and IV amiodarone (87% vs. 29%). However, ibutilide is associated with sustained polymorphic ventricular tachycardia (VT) in 1.2% to 1.7% of cases, and nonsustained VT in 1.8% to 6.7%, which is more likely to occur in patients with reduced left ventricular ejection fraction (LVEF). The risk of VT lingers for 6 or even 8 hours after ibutilide administration, regardless of whether it has terminated AFL; thus patients should not be given this medication in an emergency room setting without observing them on continuous heart rhythm monitoring for this duration. Pretreatment with magnesium can increase the efficacy and reduce the risk of torsades de pointes.²³

Oral dofetilide is also effective for conversion of AFL (70% to 80% conversion rate), more so than in AF. In the majority of patients, conversion to NSR is achieved within 36 hours. However, dofetilide can be associated with proarrhythmia, and its initiation requires continuous

cardiac monitoring for a minimum of 72 hours. IV dofetilide, which is not available in the United States, also appears to be effective for conversion of AFL, and was found to have significantly higher efficacy than IV amiodarone (75% vs. 10%).²³

Because of the limited efficacy and the associated risk of proarrhythmia, chemical cardioversion is generally reserved for selected patients, especially when electrical cardioversion is not feasible because of contraindication to sedation. In addition, when the use of long-term antiarrhythmic medications is planned for the maintenance of NSR, starting drug therapy before electrical cardioversion can be beneficial, as it can help restore NSR in some patients and obviate the need for electrical cardioversion and, in other cases, can potentially enhance the efficacy of electrical cardioversion. In addition, it can help maintain NSR after successful cardioversion and, if a side effect develops that would preclude long term use of the drug, it can be stopped and a different medication tried before the electrical cardioversion is performed.

Importantly, adequate rate control with AVN blockers (beta-blockers, diltiazem, verapamil) should be achieved before instituting class IA (procainamide and disopyramide) or IC drugs (propafenone and flecainide), which can potentially slow the flutter rate and hence facilitate 1:1 AV conduction and paradoxically faster ventricular rates.

Catheter Ablation

Catheter ablation is the definitive treatment for AFL, and it is a reasonable option for restoration of NSR for stable patients who do not require immediate cardioversion and can wait until this procedure is performed. In fact, the presence of the arrhythmia at the time of the procedure helps reliably establish the diagnosis and mechanism of the clinical arrhythmia and differentiate it from other arrhythmias that might be inducible by programmed electrical stimulation but may not be of clinical significance.

Maintenance of Sinus Rhythm

When AFL occurs as part of an acute disease process, such as hyperthyroidism, acute MI, pulmonary embolism, or following cardiac surgery, chronic therapy for the arrhythmia is usually not required after sinus rhythm is restored. In patients with no underlying reversible disorder, the risk of arrhythmia recurrence after initial restoration of NSR is high and hence strategies to maintain NSR should be considered. When long-term rhythm control is required, catheter ablation is superior to antiarrhythmic drugs and is the preferred strategy in most patients.

Catheter Ablation

Catheter ablation is recommended as first-line therapy for most patients with symptomatic or recurrent typical AFL, whether paroxysmal or persistent. The ablation procedure is associated with high long-term success rates (92% after a single procedure and 97% after multiple procedures), and low risk of serious complications (0.4%). In addition to improvement of symptoms and quality of life, successful ablation offers a potential cure of the arrhythmia, reducing the risk of thromboembolism, and potentially eliminating the need for long-term anticoagulation and antiarrhythmic drug therapy.²³

Antiarrhythmic Drug Therapy

Complete maintenance of NSR often is unachievable with current drug therapy. The average 1-year recurrence rate associated with dofetilide is more than 35%, and is even higher for flecainide (approximately 50%). Data are limited regarding the efficacy of other drugs, as most studies combined AFL with AF, with the vast majority of the patients having AF, and without specifying the results for each arrhythmia. Given the significant superiority of catheter ablation and its low complication

rate, long-term antiarrhythmic drug therapy is no longer recommended for most patients with AFL.²³

For patients in whom catheter ablation is not feasible, or when long-term antiarrhythmic drug therapy is preferred, the choice of the antiarrhythmic agent is similar to that used for rhythm control in AF (see Chapter 15). The selection of pharmacological agents (sotalol, dofetilide, amiodarone, flecainide, and propafenone) is largely driven by the safety profile, and should consider coexisting sinus nodal or AVN disease, heart failure, associated therapies, and comorbidities. The presence and extent of concomitant cardiovascular disease have to be carefully considered. A safer, although possibly less efficacious, drug is usually recommended before resorting to more effective but less safe therapies.

Prevention of Thromboembolism

AFL is associated with increased risk of systemic thromboembolism, although likely to a lesser degree than in AF. The risk factors for development of embolic events in AFL are similar to those described for AF. Short-term stroke risk following cardioversion of AFL ranges from 0% to 7%, and the annual thromboembolism rate in patients with sustained AFL is approximately 3%. Therefore the indications for long-term and for peri-cardioversion anticoagulation in patients with AFL are the same as those in patients with AF (see Chapter 15).²³

Management of Coexistent Atrial Flutter and Atrial Fibrillation

AF and AFL frequently coexist in the same patient. Clinical AFL occurs in more than one-third of patients with AF. In these patients, when AF is the predominant arrhythmia, catheter ablation of AFL unlikely would improve clinical outcome. On the other hand, when AFL is the dominant clinical arrhythmia, or when new-onset AFL develops in patients with AF after administering antiarrhythmic drug therapy, hybrid therapy (CTI ablation plus antiarrhythmic medications) can be effective.²³ Ablation of the CTI eliminates the flutter and provides good symptomatic relief, while antiarrhythmic drug therapy is continued to suppress AF. Alternatively, a combined approach of PV antrum isolation plus CTI ablation may be considered. Notably, PV isolation alone (without CTI ablation) was found in small studies to be equally effective in the suppression of both AF and AFL in these patients.

Importantly, the incidence of AF is very high among patients who initially present with isolated AFL, even after ablation of the CTI. Given the fact that up to 82% of patients with “isolated” AFL eventually develop AF, some investigators have proposed additional PV isolation at the time of CTI ablation to improve long-term freedom of AF recurrences. Although small studies suggested some value of this approach, this strategy cannot be recommended for general adoption before confirmation by larger studies because of the increased procedural risk.¹⁹

Anticoagulation therapy is commonly discontinued 1 month after a successful AFL ablation if no other atrial arrhythmias are apparent. However, given the high risk of development of new-onset AF, which is often asymptomatic, patients with typical AFL undergoing successful ablation seem to have an elevated future risk for strokes. Hence intensified cardiac monitoring and anticoagulation therapy may be necessary in this patient population, especially those with significant risk factors (such as obstructive sleep apnea and LA dilation) for developing AF. This is especially important because intermittent and symptom-based surveillance with ambulatory cardiac monitoring is inaccurate and unreliable for identifying patients with AF. However, the current practice guidelines do not provide adequate recommendations regarding the optimal monitoring and anticoagulation strategies for this patient population.^{30,31}

ELECTROCARDIOGRAPHIC FEATURES

Flutter Waves

Flutter waves appear as atrial complexes of constant morphology, polarity, and CL. Typically, flutter waves are most prominent in the inferior leads (II, III, aVF) and lead V1. In counterclockwise AFL (Fig. 12.6), the flutter waves in the inferior leads resemble a picket fence (sawtooth) because these leads are primarily negative. This pattern consists of a downsloping segment, followed by a sharper negative deflection, and then a sharp positive deflection, with a positive overshoot leading to the next downsloping plateau. The relative size of each component can vary markedly. The flutter waves can exhibit pure negative deflections in the inferior leads, negative and then positive deflections that are equal in size, or a small negative and then a larger positive deflection. Those three varieties coexist with tall positive, small positive, or biphasic P waves in lead V1, respectively. With progression across the precordium, the initial component rapidly becomes inverted and the second component isoelectric usually by lead V2 to V3. This produces the overall impression of an upright flutter wave in lead V1, which becomes inverted by lead V6. A negative deflection always precedes the positive deflection in the inferior leads in counterclockwise AFL, and the degree of positivity in the inferior leads appears to be related to the coexistence of heart disease and LA enlargement. Lead I is low-amplitude isoelectric, and lead aVL is usually upright.³²

The initial part of negative deflections showing gradual voltage decline coincides with activation of the CTI. This short period of relative electrical silence on the surface ECG is related to the small amount of tissue being activated within the isthmus. Then, the sharp negative deflection of flutter wave is caused by caudocranial activation of the interatrial septum and the LA. On the other hand, the upstroke of flutter wave and terminal deflection (from the nadir to terminal deflection point) represent craniocaudal activation in the RA free wall (eFig. 12.2). The absence of positive terminal deflection has been correlated with a greater extent of low voltage area in the RA free wall. In addition, the overall amplitude of the flutter wave, which can be a determinant of the size of positive terminal deflection, depends on the longitudinally directed vector of the RA free wall activation.³³

The surface ECG appearance of clockwise typical AFL is more variable than that of counterclockwise typical AFL, but in many respects, clockwise AFL presents an inversion of the appearance in counterclockwise AFL (see Fig. 12.6). Clockwise AFL generally has broad positive deflections in the inferior leads, with characteristic notching; however, there is an inverted component preceding the upright notched component. Depending on the amplitude of this component, the appearance can be of continuous undulation without an obviously predominant upright or inverted component. On other occasions, it may appear that the inverted component is dominant, thus superficially mimicking counterclockwise AFL. Lead V1 is characterized by a wide negative and usually notched deflection. There is transition across the precordium to an upright deflection in lead V6. Lead I is usually upright, and lead aVL is low-amplitude negative and notched.³²

Typical AFL usually has an atrial rate of 240 to 340 beats/min. However, the flutter rate can be slower in patients with conduction delays in the atrial circuit secondary to prior incomplete CTI ablation (Fig. 12.7), scars from prior cardiac surgery, or antiarrhythmic drugs, whereby flutter CLs as long as 450 milliseconds (i.e., atrial rate less than 150 beats/min) can be observed. If the ventricular response is half the atrial rate, it can be difficult to identify flutter waves “buried” within the QRS or T waves (Fig. 12.8). Close inspection of the QRS and T waves, and comparisons with ECGs obtained in normal sinus rhythm, can help identify buried flutter waves. Furthermore, vagal maneuvers

and AVN blockers can slow AV conduction and unmask the flutter waves (eFig. 12.3).

In patients who have undergone extensive LA ablation for treatment of AF, the P wave morphology during typical CTI-dependent AFL can be very different from the prior description because of alteration of intraatrial and interatrial wavefront propagation. Similarly, non-CTI-dependent macroreentrant ATs can mimic typical CTI-dependent AFL on the surface ECG. Thus arrhythmias that appear to be typical AFL may not be, whereas others that are actually typical AFL may not appear to be.

Atrioventricular Conduction

In general, AV conduction during AFL is characterized by even-integral conduction ratios; for example, with an atrial rate 300/min, the ventricular response is often 150/min or 75/min, not 90 to 100/min, as is often seen in AF. Most commonly, 2:1 AV conduction is present during AFL. Variable AV conduction and larger multiples (e.g., 4:1 or 6:1) are not uncommon. When present, variable AV conduction is the result of multilevel block; for example, proximal 2:1 AV block and more distal 3:2 Wenckebach block result in 5:2 AV Wenckebach block.

Slowing the atrial rate during AFL caused by antiarrhythmic drugs or following a prior incomplete CTI ablation can result in a paradoxical increase in the ventricular rate caused by better AVN conduction of the slower flutter beats (Fig. 12.9). For this reason, it is essential that adequate AVN blockade with beta-blockers or calcium channel blockers is in place before administering antiarrhythmic drugs that can slow the atrial rate during flutter. Rapid 1:1 AV conduction is most commonly

seen in patients with anterogradely conducting AV BTs (Fig. 12.10), but it may also be present in cases of enhanced AVN conduction secondary to high sympathetic tone (e.g., exercise, sympathomimetic drugs).

QRS Morphology

The QRS complex during AFL is often identical to that during sinus rhythm. However, the atrial impulses can be aberrantly conducted because of functional bundle branch block, most frequently right bundle branch block (RBBB) (see Fig. 12.9). Even with normal ventricular conduction, the QRS complex can be slightly distorted by temporal superimposition of flutter waves on the QRS complex. Thus the QRS complex can appear to acquire a new or larger R, S, or Q wave.

ELECTROPHYSIOLOGICAL TESTING

Typically a decapolar catheter (positioned into the CS with the proximal electrodes bracketing the CS os) and a multipolar (20 or 24 pole) Halo catheter (positioned at the tricuspid annulus) are used to map typical AFL. The distal tip of the Halo catheter is positioned at 6 to 7 o'clock in the LAO view, so that the distal electrodes will record the middle and lateral aspects of the CTI, the middle electrodes will record the anterolateral RA, and the proximal electrodes may record the RA septum (depending on the catheter used and RA size). Instead of the Halo and CS catheters, some operators use a single duodecapolar catheter around the tricuspid annulus, thus extending the catheter tip inside the CS. Such a catheter can straddle the CTI and provide recording and pacing from the medial and lateral aspects of the isthmus,

eFig. 12.3 Effects of Adenosine on Atrial Flutter (AFL). Continuous rhythm strip is shown. At left, typical AFL with 2:1 atrioventricular (AV) conduction is observed. The flutter waves are not readily visualized. Administration of intravenous adenosine causing block in the AV node resulting in a long ventricular pause and unmasking of the flutter waves. Also, adenosine results in an increase in the atrial rate and then degeneration into atrial fibrillation.

Fig. 12.7 Surface 12-Lead Electrocardiograms During Counterclockwise (*Left*) and Clockwise (*Right*) Typical Atrial Flutter (AFL) in a Patient on Flecainide Therapy. Note the slow flutter cycle length (approximately 350 milliseconds) secondary to the effects of flecainide.

Fig. 12.8 Surface 12-Lead Electrocardiogram of Typical Atrial Flutter (AFL) and Atrial Fibrillation (AF). Counterclockwise typical AFL with 2:1 atrioventricular (AV) conduction (A) and with 4:1 AV conduction (B). Note that when the ventricular response is half the atrial rate, it is difficult to identify flutter waves “buried” within the QRS or T waves (A). However, when the ventricular rate is slowed, flutter wave morphology becomes more easily visualized.

Fig. 12.8, cont'd (C) AF developed in the same patient after ablation of the cavotricuspid isthmus. Note that fibrillation waves are coarse and can mimic Q waves; however, close inspection reveals changes in rate and morphology of atrial activity that are inconsistent with AFL.

assuming good catheter-tissue contact at these locations. In the latter arrangement, however, the body of the duodecapolar catheter crossing over the CTI can potentially hinder manipulation and positioning of the ablation catheter tip to achieve adequate tissue contact for effective ablation.

Induction of Tachycardia

Programmed electrical stimulation protocol typically involves atrial burst pacing from the high RA and CS (down to the PCL, at which 2:1 atrial capture occurs) and single and double AESs (down to the atrial effective refractory period [ERP]) at multiple CLs (600 to 200 milliseconds) from the high RA and CS. Administration of an isoproterenol infusion (1 to 4 $\mu\text{g}/\text{min}$) may be required to facilitate tachycardia induction.

AFL can be induced readily with programmed electrical stimulation in most patients with a clinical history of AFL. Reproducible initiation of counterclockwise AFL is possible in more than 95% of patients. Rapid atrial pacing is more likely to induce AFL than a single AES, but as likely as introducing two AESs. On the other hand, the frequency of single or double AESs initiating AFL is low in patients without a history of AFL (less than 10%). Counterclockwise AFL is more likely to be induced by stimulation from the CS os; conversely, clockwise AFL is more likely to be induced with low lateral RA pacing. Induction of AFL usually occurs once unidirectional CTI block develops during pacing (Fig. 12.11). Not infrequently, a run of AF of variable duration is induced first, which then converts into AFL. The faster the pacing rate and the shorter the AES coupling intervals, the more likely it will be that AF is induced, which is usually self-terminating but can be sustained in less than 10% of patients with no clinical history of AF. The significance of induction of AF in these patients is uncertain.

Tachycardia Features

Typical AFL is characterized by a constant atrial CL, polarity, morphology, and amplitude of the recorded bipolar electrograms and by the presence of a single constant macroreentrant circuit with a constant atrial activation sequence. In general, the atrial rate is very regular, with cycle-to-cycle variation of less than 2%. The atrial CL is usually between 190 and 250 milliseconds, but longer TCLs can be observed in patients receiving antiarrhythmic agents or following a prior unsuccessful ablation of the CTI. It is not uncommon for clockwise and counterclockwise AFLs to occur in the same patient, and they often have similar rates, although clockwise AFL can have a slower rate.

As noted, AFL is usually associated with 2:1 AV conduction, but variable AV conduction and larger multiples are not uncommon. Variable AV block is the result of multilevel block; for example, proximal 2:1 AV block and more distal 3:2 Wenckebach block result in 5:2 AV Wenckebach block. It is likely that the proximal 2:1 block occurs in the upper part of the AVN, whereas Wenckebach block occurs in the lower part of the AVN. Distal Wenckebach behavior in the His bundle (HB) would result in a similar AV conduction pattern but is unlikely to occur. In most cases, the nonconducted flutter impulses block in the AVN. However, infranodal AV block can occur, especially in the presence of prolonged His-Purkinje system (HPS) refractoriness caused by antiarrhythmic agents or during Wenckebach cycles in the AVN that leads to long-short cycle activation of the HPS.

The presence of an anterogradely conducting AV BT with a short refractory period can result in preexcited AFL with rapid 1:1 AV conduction. Infusion of isoproterenol can enhance AVN function and occasionally facilitate 1:1 AV conduction, especially when the atrial rate is relatively slow. Adenosine increases the degree of AV block, but

AFL with variable AV conduction

Slow AFL with variable AV conduction

Fig. 12.9 Effects of Antiarrhythmic Drugs on Typical Atrial Flutter (AFL). Baseline surface electrocardiogram in a patient with AFL and variable atrioventricular (AV) conduction (A). Treatment with propafenone results in slowing of the atrial rate during AFL (B) and a paradoxical increase in the ventricular rate caused by better AV nodal conduction of the slower flutter beats (C). Right bundle branch block aberrancy is observed during 1:1 AV conduction.

Fig. 12.9, cont'd

it also shortens atrial refractoriness and can result in the degeneration of AFL into AF (see eFig. 12.3).

Diagnostic Maneuvers During Tachycardia

Atrial Extrastimulation During Tachycardia

An AES from the high RA or CS or along the Halo catheter is introduced at a coupling CL 10 milliseconds shorter than the flutter CL, with progressive shortening of the coupling CL by 10 to 30 milliseconds.

An AES commonly results in resetting of the AFL circuit. The closer the site of atrial stimulation is to tissue in the circuit, the easier the resetting of the AFL circuit at longer coupling intervals will be. AFL has a resetting response pattern typical of reentrant circuits with fully excitable gaps: flat (for approximately 15% to 30% of the TCL, equal to approximately 30 to 63 milliseconds in the absence of drugs, and up to 100 milliseconds with class I antiarrhythmic agents) and then an increasing return CL in response to progressively shorter AES coupling intervals, indicating slowing of conduction from the stimulation site or within the circuit. The ability to capture the atrium without affecting (resetting) the AFL circuit timing indicates that the pacing site is outside the AFL circuit (e.g., RA appendage or distal CS).

It is usually difficult for a single AES to terminate AFL because AFL has a sizable fully excitable gap (15% to 30% of the TCL) that makes it difficult for a single AES to penetrate the reentrant circuit with adequate prematurity to terminate the AFL without intervening atrial refractoriness and intraatrial conduction delays. An AES delivered in the region of the CTI has the greatest chance of terminating AFL because it can capture the isthmus tissue with a very short coupling interval (close to the ERP of this critical site), given the lack of intervening tissue between the stimulation site and isthmus. Termination of AFL always occurs because of conduction block in the CTI.

Atrial Pacing During Tachycardia

Burst pacing from the CS or along the Halo catheter is started at a CL 10 to 20 milliseconds shorter than the flutter CL. Intermittent overdrive pacing is repeated at progressively shorter PCLs. The capture of atrial stimuli and acceleration of the atrial rate to the paced rate should be verified before analyzing the flutter response to pacing. The response of AFL to overdrive pacing is evaluated for overdrive suppression, acceleration, transformation into distinct uniform AFL morphologies or AF, entrainment, and the ability and pattern of termination.

Entrainment

Overdrive atrial pacing at long PCLs (i.e., 10 to 30 milliseconds shorter than the TCL) can almost always entrain typical AFL. The slower the pacing rate and the farther the pacing site from the reentrant circuit, the longer the pacing drive will need to be to penetrate and entrain the tachycardia.

Demonstration of entrainment of the AT establishes a reentrant mechanism of the tachycardia and excludes triggered activity and abnormal automaticity as potential mechanisms. However, it is important to understand that the mere acceleration of the tachycardia to the pacing rate and then resumption of the original tachycardia after cessation of pacing do not establish the presence of entrainment. After cessation of each pacing drive, the presence of entrainment should be verified by demonstrating the presence of fixed fusion of the paced complexes at a given PCL, progressive fusion at faster PCLs, and resumption of the same tachycardia morphology following cessation of pacing with a nonfused complex (see Box 5.1).^{34,35}

During entrainment of AFL, fusion of the stimulated impulse can be observed on the surface ECG, but it is easier to recognize on intra-cardiac recordings from the Halo and CS catheters. Entrainment with

Fig. 12.10 Surface 12-Lead Electrocardiograms During Clockwise Typical Atrial Flutter in a Patient With a Left Posteroseptal Bypass Tract (BT). (A) 2:1 atrioventricular (AV) conduction with QRS fusion (secondary to conduction over both the BT and the AV node). (B) 1:1 AV conduction over the BT with fully preexcited QRS morphology.

Fig. 12.11 Initiation of Counterclockwise Typical Atrial Flutter (AFL) by Atrial Pacing From the Coronary Sinus (CS). The Halo catheter is positioned around the tricuspid annulus (TA), with the distal bipole (*Halo₁₋₂*) at the lateral aspect of the cavotricuspid isthmus. Burst pacing from the CS ostium (*CS₁₋₂*) results in wavefronts proceeding in both directions around the TA, colliding around *Halo₉₋₁₀* (red and blue arrows). With progressive shortening of the pacing cycle length, the activation wavefront propagates from the pacing site at the CS ostium and blocks before arriving at *Halo₁₋₂* but propagates around the TA in a counterclockwise direction. When pacing stops, this unopposed paced wavefront continues around the TA as counterclockwise AFL, with subsequent proximal-to-distal CS activation by the tachycardia wavefront.

manifest fusion can be demonstrated with pacing from sites outside the CTI, such as lateral RA and CS. Conversely, pacing at the CTI results in entrainment with concealed fusion, whereby flutter waves (on the surface ECG and intracardiac recordings) during pacing are identical to those during the tachycardia.^{34,35}

Termination

More rapid atrial burst pacing (PCL 20 to 50 milliseconds shorter than the TCL) results in termination of AFL in most cases. Termination of AFL during rapid pacing can be indicated by a sudden change of P wave morphology on the surface ECG and by a change of atrial activation sequence in the HB and CS os recordings. This is seen particularly with high RA pacing during counterclockwise AFL, whereby on termination of AFL, the negative flutter waves in the inferior leads change suddenly into upright P waves, thus reflecting a change in the atrial activation sequence to one of high RA pacing (i.e., simultaneous RA lateral and septal activation in a craniocaudal direction). However, if the pacing site is distant from the AFL circuit (e.g., distal CS), a large mass of the atrial tissue can be captured by the pacing stimulus, to produce a marked change in P wave morphology (i.e., manifest fusion) without terminating the AFL.

Failure to terminate AFL with rapid pacing can be caused by any of the following: (1) the pacing rate is not fast enough to impinge on the tail of tissue refractoriness; (2) a short period of pacing (the closer the PCL is to the TCL, the longer the pacing duration will need to be to terminate the tachycardia); (3) a pacing site distant from the AFL circuit, with the intervening atrial tissue preventing penetration of the

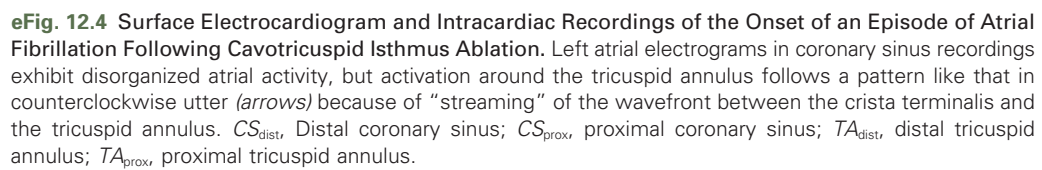

AFL circuit; or (4) the possibility that an apparent AFL on the ECG may actually be AF with “streaming” of the RA activation wavefront or may be a focal nonreentrant AT (eFig. 12.4).

Overdrive Suppression

Overdrive suppression analogous to that seen with automatic AT is not expected in AFL. The postpacing interval (PPI) (measured from the last pacing stimulus that entrained the tachycardia to the next near-field recorded electrogram at the pacing site) remains relatively stable when entrainment of AFL is performed from the same endocardial site, regardless of the length of the pacing drive. This is in contrast to overdrive suppression seen in automatic ATs, which would be associated with progressive delay of the first tachycardia beat return cycle with progressively longer overdrive pacing drives.

Acceleration

Acceleration by overdrive pacing refers to sustained shortening of the TCL following cessation of pacing. Rarely, atrial pacing can accelerate AFL into one of two different tachycardias: double-wave reentry or lower loop reentry. Double-wave reentry is manifest by acceleration of the tachycardia rate but with identical surface and intracardiac electrogram morphology, and it can be recognized by having simultaneous activation of the superior and inferior regions of the tricuspid annulus, with all activation being sequential. This rhythm rarely lasts for more than a few beats and may serve as a trigger for AF. Lower loop reentry is a form of CTI-dependent AFL with a reentrant circuit around the IVC. This arrhythmia is usually transient

and terminates by itself or converts spontaneously into AFL or AF (see Chapter 13).^{36,37}

Transformation

Rapid atrial burst pacing can convert AFL into AF. This is less likely with a slower PCL or pacing from sites within the AFL circuit. Induction of other forms of atrial macroreentry can also be observed, especially with faster pacing rates.

MAPPING

Activation Mapping

The simultaneous recording from endocardial sites around the tricuspid annulus (which encompasses most of the flutter macroreentrant circuit) by the Halo and CS catheters significantly facilitates activation mapping during typical AFL, and sequential point-by-point activation mapping is usually not required.

The RA activation sequence during counterclockwise AFL occurs sequentially down the lateral RA wall and adjacent to the crista terminalis, across the CTI (with some delay because of slow conduction across the CTI), past the CS os, up the atrial septum, over the roof of the RA, and back to the lateral free wall of the RA (in a proximal-to-distal direction along the Halo electrodes; see Fig. 12.1). This sequence is reversed during clockwise AFL (see Fig. 12.1). In both types of typical AFL (counterclockwise and clockwise), activation of the CS propagates in a proximal-to-distal direction. Notably, double potentials are seen on the crista terminalis and along the eustachian ridge and indicate lines of block (fixed or functional) along those structures.¹⁰

The atrial activation sequence in AFL is different from that during sinus rhythm or focal AT originating from the upper RA or LA, in which the activation wavefront propagates from the upper RA (middle or proximal Halo electrodes) down both the RA septum and lateral wall in a craniocaudal direction, toward the distal and proximal-most Halo electrodes.

Occasionally P wave morphology on the surface ECG resembles typical AFL, but intracardiac recordings show parts of the atria (commonly the LA) exhibiting disorganized atrial activity (see eFig. 12.4). Such rhythms behave more like AF than AFL, but they may be converted to true typical AFL with antiarrhythmic drugs.

As noted, double-wave reentry is characterized by an activation sequence identical to that of typical AFL, but at a faster atrial rate and with simultaneous activation of the superior and inferior regions of the tricuspid annulus, with all activation being sequential.

Entrainment Mapping

Entrainment mapping provides information about sites of the RA or LA that are part of the reentrant circuit, those that are outside the circuit, and the critical isthmus in the macroreentrant circuit. Entrainment also qualitatively estimates how far the reentrant circuit is from the pacing site. For entrainment mapping, atrial pacing is typically performed from the CTI, high RA, mid-lateral RA, and proximal and distal CS at PCLs 10 to 30 milliseconds shorter than the TCL.^{38–40}

Before attempting to use entrainment methods for mapping, it is necessary first to demonstrate that the tachycardia can be entrained, thus providing strong evidence that it is caused by reentry rather than by triggered activity or automaticity (see Box 5.2). At sites of entrainment, there should be confirmation of consistent capture of the atrium at the PCL for several beats with minimal or no change in the surface morphology or intracardiac electrograms and continuation of the identical tachycardia after pacing. Evaluation of the PPI or other criteria is meaningless (or even worse, misleading) when the presence of true entrainment has not been established. In addition, it is important to

verify the absence of termination and reinitiation of the tachycardia during the same pacing drive, or transformation of the AFL into a different tachycardia (evident as a change in CL or activation sequence, or both) following cessation of pacing.¹³

Once the presence of entrainment is verified, several criteria can be used to indicate the relation of the pacing site to the reentrant circuit. As discussed in detail in Chapter 13, the first entrainment criterion to be sought is concealed fusion. Entrainment with concealed fusion indicates that the pacing site is in a protected isthmus located within or attached to the reentrant circuit. Whether this protected isthmus is crucial to the reentrant circuit or just a bystander site needs to be verified by other criteria, mainly comparing the PPI with the TCL and the stimulus-exit interval with the electrogram-exit interval (Fig. 12.12). The diagnosis of CTI-dependent AFL is established when pacing from the CTI results in entrainment with concealed fusion and a PPI that is equal (within 20 milliseconds) to the flutter CL and an electrogram-exit interval that is equal (within 20 milliseconds) to the stimulus-exit interval. During counterclockwise AFL, a site medial to the CTI, such as the CS os, may be used to represent the exit of the reentrant wavefront. Conversely, in clockwise AFL, a site lateral to the tricuspid annulus, such as the distal Halo electrode, may be used (Box 12.1).^{34,35}

It is important to recognize that the PPI–TCL value can be misleadingly long despite pacing from sites within the reentrant circuit. In one report in patients with typical AFL, long PPI–TCL values (more than 30 milliseconds) after entrainment from the CTI were observed in 18% of patients despite a PCL within 20 milliseconds of the TCL, and more frequently when the PCL was 30 milliseconds shorter than the TCL and in patients on amiodarone therapy. The long PPI–TCL values are likely

BOX 12.1 Entrainment Mapping of Typical Atrial Flutter

Pacing from sites *outside* the AFL circuit (e.g., from RA appendage or middle or distal CS) results in the following:

- Manifest atrial fusion on the surface ECG or intracardiac recordings (fixed fusion at a single PCL and progressive fusion on progressively shorter PCLs)
- $PPI - TCL > 20$ ms
- The interval between the stimulus artifact to the onset of the flutter wave on the surface ECG is longer than the interval between the local electrogram on the pacing site to the onset of the flutter wave on the surface ECG

Pacing from sites *inside* the AFL circuit (e.g., from the CS os or around the tricuspid annulus) results in the following:

- Manifest atrial fusion on surface ECG or intracardiac recordings (fixed fusion at a single PCL and progressive fusion on progressively shorter PCL)
- $PPI - TCL < 20$ ms
- The interval between the stimulus artifact to the onset of the flutter wave on the surface ECG is equal to the interval between the local electrogram on the pacing site to the onset of the flutter wave on the surface ECG

Pacing from a protected isthmus inside the circuit (cavotricuspid isthmus) results in the following:

- Concealed atrial fusion (i.e., paced atrial waveform on the surface ECG and intracardiac recordings is identical to the AFL waveform)
- $PPI - TCL < 20$ ms
- The interval between the stimulus artifact to the onset of the flutter wave on the surface ECG is equal to the interval between the local electrogram on the pacing site to the onset of the flutter wave on the surface ECG

AFL, Atrial flutter; CL, cycle length; CS, coronary sinus; CS os, coronary sinus ostium; ECG, electrocardiogram; PCL, pacing cycle length; PPI, postpacing interval; RA, right atrium; TCL, tachycardia cycle length.

Fig. 12.12 Entrainment of Counterclockwise Typical Atrial Flutter (AFL). (A) Entrainment from the distal coronary sinus (CS) results in manifest atrial fusion and a long postpacing interval (PPI; PPI – AFL cycle length [CL] = 80 milliseconds) because the distal CS is far from the reentrant circuit. (B) Entrainment from ablation catheter positioned at the cavotricuspid isthmus (CTI) results in concealed atrial fusion with a short PPI (PPI – AFL CL = 14 milliseconds), a finding indicating that the CTI is part of the reentrant circuit. *Continued*

Fig. 12.12, cont'd (C) Entrainment from the lateral right atrial wall is attempted; however, the last paced stimulus fails to capture the 12 atrium (*open arrow*); therefore calculation of the PPI in this case is invalid and produces erroneous results. ABL, Ablation site; CS_{dist}, distal coronary sinus; CS_{prox}, proximal coronary sinus; PCL, pacing cycle length; RA, right atrium; TA_{dist}, distal tricuspid annulus; TA_{prox}, proximal tricuspid annulus.

caused by rate-dependent slowing of conduction or alterations of the activation path. Entrainment from near the IVC in the mid CTI may help minimize the chances of a misleading PPI value. These findings may also apply to other macroreentrant tachycardias.^{41,42}

Using the “number needed to entrain” criterion can overcome these pitfalls. The number needed to entrain assesses the number of captured pacing stimuli required to accelerate tachycardia to the PCL. Recording electrograms from the lateral RA and distal CS and properly timed initiation of the entrainment pacing (the coupling interval of the first paced stimulus is identical to the PCL) are required to measure the number needed to entrain. A small number (1 or 2) of pacing stimuli needed to entrain (with a PCL of 5 to 30 milliseconds shorter than the TCL) is consistent with a PPI–TCL value of less than 20 milliseconds and indicates that the pacing site is within the reentry circuit. A larger number of pacing stimuli needed to entrain (>3 for PCLs of 16 to 50 milliseconds, and >4 for PCLs of 5 to 15 milliseconds shorter than the TCL) indicates that the pacing site is outside the reentry circuit.⁴³ An advantage of this criterion is that it does not require the continuation of tachycardia after pacing for assessment and remains valid even when the tachycardia terminates or changes. The number needed to entrain is also useful when electrograms for assessment of the PPI are difficult to define. In addition, the number needed to entrain does not increase at shorter PCLs, likely because the conduction velocity in the intervening myocardium (between the pacing site and the reentry circuit) is less susceptible to changes in the PCL. This is in contrast to the slow

conduction zone within the reentry circuit, which can display decremental conduction properties at PCLs shorter than the TCL, resulting in misleading long PPIs.⁴³

Electroanatomic Mapping

Although atrial activation sequences in the Halo and CS catheters combined with entrainment mapping techniques are usually adequate to confirm the diagnosis of CTI-dependent typical AFL and facilitate ablation of the CTI, electroanatomic 3-D mapping (CARTO mapping system [Biosense Webster, Diamond Bar, CA], EnSite system [St. Jude Medical, St. Paul, MN], or Rhythmia [Boston Scientific Corp., Marlborough, MA]) can help distinguish between a focal origin and macroreentrant tachycardia by providing a precise description of the macroreentrant circuit and sequence of atrial activation during the tachycardia and rapid visualization of the activation wavefront.

Initially, selection of the reference electrogram, positioning of the anatomical reference, and determination of the window of interest are undertaken. The reference catheter is usually placed in the CS (because of its stability), and an electrode recording a prominent atrial electrogram is selected, thus ensuring that the ventricular electrogram is not the one detected by the system.

The mapping catheter is initially positioned, using fluoroscopy, at known anatomical points that serve as landmarks for the electroanatomic map. Anatomical and EP landmarks (IVC, SVC, CS, HB, and tricuspid annulus) are tagged. A set of six specific points (three at the

tricuspid annulus and three at the mouth of the IVC) is acquired to delineate the individual isthmus anatomy. Activation mapping is performed to define the atrial activation sequence. The catheter is moved slowly around the chamber walls to sample multiple points along the endocardium, thereby sequentially acquiring the location of its tip together with the local electrogram. Reasonable numbers of points are homogeneously distributed in the RA, with careful mapping of endocardial sites around the tricuspid annulus and CTI. The local activation time at each site is determined from the intracardiac bipolar electrogram and is measured in relation to the fixed intracardiac electrogram obtained from the CS (reference) catheter. The activation map may also be used to catalog sites at which pacing maneuvers are performed during assessment of the tachycardia (e.g., sites with good pace maps). Activation maps display the local activation time by a color-coded overlay on the reconstructed 3-D geometry. The selected points of local activation time are color-coded.

The 3-D electroanatomic activation map typically demonstrates a continuous progression of colors around the tricuspid annulus with close proximity of earliest and latest local activation and an activation time in a similar range to TCL, consistent with macroreentry (Fig. 12.13; see Figs. 6.8 and 6.13). During counterclockwise AFL, the activation wavefront exits the CTI as a broad wavefront, spreading anterosuperiorly around the tricuspid annulus, as well as posterosuperiorly in the RA. Lateral spread of the posterior wavefront is blocked along the vertical line in the posterolateral RA, a region marked by double potentials that coincides with the crista terminalis. The posterior wavefront propagates cranially around the SVC to merge with the activation wavefront circulating around the tricuspid annulus. The anterolateral wall of the RA is the last to activate as the wavefront reenters the lateral aspect of the CTI. Importantly, the location where earliest activation and latest local activation meet can be anywhere along the reentry circuit, depending on the timing of the electrical reference (the zero point) chosen for activation mapping (see Fig. 6.11). That location, like in the case of any macroreentrant tachycardia, has no relation to the site of the critical isthmus of the reentry circuit.

Activation mapping of the LA during typical AFL characteristically demonstrates earliest activation of at the interatrial septum or CS os, and activation of the whole LA chamber usually comprises only a portion of the atrial CL (Fig. 12.14).

The 3-D electroanatomic maps can also provide information about the voltage characteristics of the tissues involved in the CTI. The lower the voltage, the easier it is to achieve block in the tissue. Thus 3-D electroanatomic mapping can potentially help select a path in the CTI that is easier to ablate—a path that may not necessarily be the shortest across the isthmus.

Noncontact Mapping

The EnSite 3000 noncontact mapping system (St. Jude Medical) consists of a noncontact catheter with a multielectrode array surrounding a 7.5-mL balloon mounted at the distal end. The 9 Fr balloon catheter is advanced over a 0.035-inch guidewire under fluoroscopy guidance and is positioned in the middle and lower portion of the RA. The balloon is positioned in the center of the RA and does not come in contact with the atrial walls being mapped. IV heparin is administered before balloon deployment to keep the activated clotting time at 250 to 300 seconds. A conventional mapping-ablation catheter is used to collect geometry information. The mapping catheter is initially moved to known anatomical locations (IVC, SVC, CS, HB, and tricuspid annulus), which are tagged. Detailed geometry of the chamber is then reconstructed by moving the mapping catheter around the atrium.

After the chamber geometry is determined, mapping is started during tachycardia. The system simultaneously acquires data for the entire

chamber, and then reconstructs unipolar electrograms and superimposes them onto the virtual endocardium, to produce isopotential maps with a color range representing voltage amplitude (eFig. 12.5; see Fig. 6.21). A default high-pass filter setting of 2 Hz is used to preserve components of slow conduction on the isopotential map. Color settings are adjusted so that the color range matches 1 to 1 with the millivolt range of the electrogram deflection of interest. Activation can be tracked on the isopotential map throughout the tachycardia cycle. Isochronal maps can also be created that represent progression of activation throughout the chamber relative to a user-defined electrical reference timing point.

Although typical AFL is usually readily treated using standard ablation techniques, noncontact mapping can be used to confirm the anatomical location of the flutter circuit, reduce fluoroscopy time, and confirm CTI block after ablation. Noncontact mapping has also been used to identify and guide radiofrequency (RF) ablation of the site of residual conduction following incomplete linear ablation lesions at the isthmus. Because of its ability to record from multiple sites simultaneously, noncontact mapping can rapidly identify gaps in linear lesions. This is accomplished by analysis of one or more paced complexes originating adjacent to the line being assessed. This capability can be particularly helpful in patients who have recurrent AFL following a previous ablation. Because any number of maps can be superimposed on the initial geometry, bidirectional block at the ablation site can be rapidly identified during pacing following ablation. Tagging ablation areas during delivery of each RF impulse and a constantly visible ablation line offer another advantage—they ensure that no area is overlooked or ablated repeatedly.

ABLATION

Target of Ablation

The CTI is the ideal target of AFL ablation because it is accessible, relatively narrow, short, safe to ablate, and essential for the AFL circuit (and not because it is the diseased area or the structure causing the AFL). The central part of the isthmus (the 6 o'clock region in a fluoroscopic LAO view) appears to be the optimal target site because it is the narrowest part of the isthmus (19 ± 4 mm; range, 13 to 26 mm) and relatively thin and therefore is less likely to resist RF ablation. Other advantages of the central isthmus are the increased distance from the paraseptal isthmus, which contains extensions of the AVN or AVN artery in 10% of patients, and the increased distance from the inferolateral isthmus, where the right coronary artery is in close proximity (less than 4 mm) to the endocardium.³

Alternatively, the tricuspid annulus-CS or IVC-CS isthmuses may be targeted (Fig. 12.15). However, for this approach to be successful, ablation within the CS is frequently necessary. Such approaches are less successful in curing AFL. The paraseptal isthmus (tricuspid annulus-CS isthmus) has the thickest wall, compared with other parts of the inferior RA isthmus, although there is significant interindividual variability, and this structure is close to the arterial branch supplying the AVN and, in some cases, can contain the inferior extensions of the AVN. The inferolateral isthmus is the longest portion and is in closest proximity to the right coronary artery.

Ablation Technique

Periprocedural Anticoagulation

In patients with persistent AFL of a duration longer than 48 hours or unknown duration, catheter ablation should be delayed until the patient has been anticoagulated at appropriate levels for 3 to 4 weeks or TEE has excluded atrial thrombi. In these patients, several options exist for periprocedural anticoagulation. Traditionally, a “bridging” strategy of

Fig. 12.13 Three-Dimensional Electroanatomic (CARTO) Mapping of Typical Atrial Flutter (AFL). (A) Three-dimensional electroanatomic (CARTO) activation map of the right atrium (RA) in the left anterior oblique view constructed during counterclockwise typical AFL. During tachycardia, the depolarization wavefront travels counterclockwise around the tricuspid annulus (TA), as indicated by a continuous progression of colors (from red to purple) with close proximity of earliest and latest local activation (red meeting purple). Linear ablation (red dots) is performed across the cavotricuspid isthmus. (B to G) Propagation map of the RA during counterclockwise typical AFL (arrows). CS, Coronary sinus; IVC, inferior vena cava; SVC, superior vena cava.

Fig. 12.14 Biatrial Electroanatomic Activation Mapping (Rhythmia) During Typical Counterclockwise Atrial Flutter (AFL). Maps are shown in the right anterior oblique views. (A) Activation map of the right atrium (RA) demonstrates propagation of the depolarization wavefront in a counterclockwise direction around the tricuspid annulus (TA), as indicated by a continuous progression of colors (from red to purple) with close proximity of earliest and latest local activation. Activation of the whole RA chamber extended over the entire atrial cycle length (CL, 263 milliseconds). (B) Activation map of the left atrium (LA) demonstrates focal-like activation pattern with the earliest activation located at the inter-atrial septum and coronary sinus (CS) ostium. Note and activation of the whole LA chamber comprised only half of the atrial CL (127 milliseconds out of 263 milliseconds). (C) Biatrial activation map now reveals that the flutter circuit is entirely confined within the RA, while LA activation occurs as a bystander and follows transseptal conduction across the inferior CS-LA connection, Bachmann's bundle, and/or fossa ovalis. LAA, LA appendage; MA, mitral annulus; RIPV, right inferior pulmonary vein; RSPV, right superior pulmonary vein; SVC, superior vena cava.

conversion of oral anticoagulation therapy to enoxaparin was employed to allow ablation and subsequent hemostasis to be performed during a pause in anticoagulation. Alternatively, catheter ablation may be performed on uninterrupted periprocedural oral anticoagulation (warfarin, dabigatran, factor Xa inhibitors).²⁹

Catheter Positioning

Commonly, a standard large-tip (8-mm) or an irrigated-tip ablation catheter is used. The catheter's curve size and shape can affect the ability to position the catheter on the CTI. Compared to standard 4- or 5-mm-tip ablation catheters, RF ablation catheters with a large distal electrode

Fig. 12.16 Fluoroscopy of Catheter Ablation of the Cavotricuspid Isthmus. Fluoroscopic views (right anterior oblique [RAO] and left anterior oblique [LAO]) illustrating catheter location during ablation (Abl) of the cavotricuspid isthmus. CS, Coronary sinus.

and irrigated-tip catheters allow the creation of larger lesions in high- and low-flow regions and facilitate ablation of the CTI by achieving a high success rate with a smaller number of RF lesions, shorter procedure times, and less fluoroscopy exposure.

Catheters with larger curves are generally preferred to ensure adequate reach of the ablation electrode to the tricuspid annulus. Also, the use of preshaped guiding sheaths (e.g., SR0, SL1, or ramp sheath; Daig, Minnetonka, MN) can help extend the reach of the catheter tip across the CTI, stabilize the ablation electrode position, and prevent the catheter from sliding off the CTI and in and out of the right ventricle (RV).

The CTI can be localized electroanatomically. The ablation catheter is advanced to the RV under fluoroscopy (right anterior oblique [RAO] view); the tip is deflected to achieve contact with the RV inferior wall and is withdrawn progressively until it records small atrial and large ventricular electrograms. The distal tip of the ablation catheter is then adjusted in the LAO fluoroscopy view until it is midway on the CTI, between the atrial septum and RA lateral wall (pointing toward 6 o'clock in a 45-degree LAO view; Fig. 12.16).

The ratio of the atrial and ventricular electrogram amplitude (A/V ratio) can help localize the position of the ablation catheter across the CTI; the A/V ratio is typically 1:4 or less at the tricuspid annulus, 1:2 to 1:1 at the CTI, and 2:1 to 4:1 near the IVC. The location of the catheter at the CTI can also be confirmed by demonstrating entrainment with concealed fusion during AFL.

Radiofrequency Ablation

The ablation catheter is initially positioned on or near the tricuspid annulus, where ablation is commenced. Then the catheter is gradually withdrawn toward the IVC either during continuous RF energy application or in a sequentially interrupted point-by-point application of RF energy. RF lesions are applied for 30 to 60 seconds at each location, with a power output of 50 to 70 W targeting a temperature of 55°C to 65°C for standard 8-mm-tip ablation, and 40 to 50 W with a temperature limit of 40°C to 45°C for irrigated ablation. With closely spaced RF applications using a nonirrigated electrode (i.e., 4- or 8-mm electrodes), coagulum formation or charring can occur on the electrode and preclude further energy delivery to tissue until the electrode has been cleaned after withdrawing it from the body.

The first RF lesion is initiated from the tricuspid annulus edge with large ventricular and small atrial electrograms, and the last lesion is completed at the IVC edge. It is important that linear lesions span

completely from the tricuspid annulus to the IVC (see Fig. 12.13). After each RF application, the electrogram loses voltage and can become fragmented; the catheter is then withdrawn (2 to 4 mm at a time) toward the IVC until a new area of sharp atrial electrogram is reached, and the next RF application is delivered. This is repeated until the disappearance of atrial electrograms indicates that the catheter has reached the IVC. Before each RF application, the position of the ablation catheter is confirmed fluoroscopically, as described, or by using a 3-D mapping-navigation system.

Ablation is typically performed during AFL or CS pacing (if the patient is in sinus rhythm at the time). When ablation is carried out during AFL, the first endpoint is to terminate AFL during RF energy delivery. During delivery of RF energy, AFL can terminate or its CL can increase transiently or permanently, and a gradual delay in activation between the CS os and the low lateral RA wall can occur. This indicates that the ablation lesions have affected the circuit and should lead to continuation of RF delivery or extension of the lesion to ensure the achievement of complete conduction block across the CTI.

When ablation is performed during sinus rhythm, it is preferable to apply RF energy during continuous CS os pacing (e.g., at PCL of 600 milliseconds). Ablation during CS os pacing allows monitoring the effects of ablation lesions on CTI conduction indicated by progressive delay in activation timing in the low lateral RA (as recorded by the Halo catheter). This helps extending ablation duration at sites where RF lesions result in noticeable delays in CTI conduction. It also helps defining the location of the RF lesion that results in CTI block (indicated by an abrupt change to purely crania-to-caudal sequential lateral RA activation terminating at the lateral side of the ablation line during CS os pacing), so that that site can be revisited if CTI conduction recovers after the initial block. Observing even subtle differences in conduction times during AFL or CS pacing can be facilitated by using a trigger sweep screen, in which two complexes are displayed: the first is aligned on the same electrogram or the stimulus artifact at each occurrence, and the complex that follows the synchronized complex can be seen to occur progressively later as conduction slows.

Not infrequently, ablation of the CTI requires more than one pass of RF delivery across the isthmus. It can be necessary to rotate the ablation catheter away from the initial line of energy application, medially or laterally in the isthmus, to create new or additional lines of ablation eventually resulting in block. At the time of the second pass-over, the ablation line isthmus electrograms will be fragmented, of low voltage, and often double.

Maximum Voltage-Guided Technique

The pectinate muscles fan out from the crista terminalis and encroach upon the CTI for variable distances. Those muscle bundles exhibit significantly heterogeneous trabecular pattern. Although bundle-to-bundle electrical communication can exist, the muscle trabeculae are frequently nonoverlapping and are separated by nonconducting fibrofatty tissue.⁴⁴

The maximum voltage-guided technique is based on the hypothesis that discrete muscle bundles in the CTI (with poor bundle-to-bundle electrical communication, as opposed to a continuous sheet) participate in the flutter circuit. Large atrial electrogram voltages identify the location of these muscle bundles along the isthmus and are selectively targeted for ablation. In effect, bidirectional CTI block is produced by the summation of a series of discrete focal ablations, rather than a continuous ablation line across the CTI. Hence the length of the isthmus that needs to be ablated could be narrower than the “anatomical” isthmus.^{44,45}

Using this technique, the CTI is mapped in the 6 o'clock position, and bipolar atrial electrograms (during AFL or, preferably, during sinus rhythm or CS pacing) are measured from peak to peak during a continuous pull-back along the isthmus. The site of maximum voltage is noted and used as a marker for a presumed muscle bundle. The ablation catheter is positioned at this site, regardless of the location along the line, and RF ablation is performed for 40 to 60 seconds until an amplitude reduction of 50% or more is achieved; complete elimination of all signal is not necessary, since the size of the electrode recording area exceeds the area of extensive damage at the catheter tip. If this ablation lesion does not result in bidirectional CTI block, the line is remapped, and the next largest atrial electrogram is targeted for ablation. This is repeated until bidirectional CTI block is achieved. This method, therefore, targets the signals with highest amplitude along the CTI and does not necessitate a contiguous line of ablation. This technique was found to reduce ablation times significantly compared with a purely anatomical approach; however, this did not translate into a reduction in fluoroscopy or overall procedure time.^{44–46}

Role of Electroanatomic Mapping Systems

Electroanatomic mapping systems (CARTO or NavX) can provide precise spatial localization and tracking of the ablation catheter along the CTI that potentially help shorten fluoroscopy time. In addition, these mapping systems enable visualization of the ablation line as the procedure is carried out so that no area is left out or repeatedly ablated. Therefore it facilitates the creation of ablation lines devoid of gaps across the entire isthmus (see Fig. 12.13).⁴⁷

To help guide ablation, the CTI anatomy needs to be defined on the mapping system. After the usual anatomical landmarks are taken, detailed CTI mapping is performed by withdrawing the catheter at 2- to 3-mm intervals and taking several points along the line. In addition, multiple points at the tricuspid annulus and at the mouth of the IVC are acquired to delineate isthmus anatomy. One specific point is acquired at the most inferior point of the tricuspid annulus, where a small atrial electrogram and a larger ventricular electrogram are recorded. The catheter is then slightly rotated to two additional points at the tricuspid annulus, 1.5 to 2 cm septally and laterally. Three points are then acquired at the mouth of the IVC: one directly opposite to the inferior point of the tricuspid annulus, and the other two points slightly lateral and medial to this point. In this way, the extent of the myocardial isthmus can be clearly defined and depicted in the 3-D space. The isthmus region forms a relatively flat rectangular surface in a caudal projection, and a side-on view is provided by the RAO projection. These views allow visualization of lateral and septal displacement of the catheter tip, as well as the distance from the tricuspid annulus and the IVC. The ablation line can be planned by a trial run across the isthmus. During RF application,

the line is placed to connect the most anterior and posterior points in the CTI; the location of each site of RF application is “tagged” on the system. Each tag is approximately 4 mm in diameter, thus permitting visual estimation of the density of applications needed to produce a linear lesion during the drag. This helps avoid redundant lesion application and can identify potential gaps in the ablation line.⁴⁷ Tags are visual tools and can be displayed as 2 mm or even 1 mm diameters to search for possible gaps in the ablation line.

Electroanatomic mapping also provides information about the voltage characteristics of the tissues within the CTI. This information can be of value in selecting ablation targets and choosing a path across the isthmus that is easier to ablate, which may not necessarily be the shortest path. Voltage mapping of the isthmus is particularly helpful in patients with recurrent AFL following previous ablation attempts; high-voltage and breakthrough sites identified during activation and voltage mapping may then be chosen as ablation targets.⁴⁷

Verification of CTI conduction block following ablation can also be performed using electroanatomic mapping. The activation wavefront during AFL halts at the previously completed line but continues through the breakthrough site (see later).

The benefits of electroanatomic mapping compared with conventional mapping for catheter ablation have been clearly demonstrated in various arrhythmia entities, such as focal and macroreentrant AT, AF, and VT. These benefits include the ability of the technology for exact anatomical reconstruction, renavigation of the catheter accurately to positions removed from fluoroscopic markers, and precise electroanatomic identification of an arrhythmia origin or reentrant circuit. In the setting of typical AFL, however, the reentrant circuit and critical isthmus can be identified in most cases by using conventional mapping and fluoroscopic methods. Therefore it is not surprising that the use of electroanatomic mapping and ablation in one report did not improve on the efficacy and the duration of the procedure as compared with the conventional technique. Nevertheless, fluoroscopy exposure time in that study was significantly reduced in the electroanatomic ablation group by almost 50%; in fact, electroanatomic mapping systems have enabled complete lack of fluoroscopic use during typical AFL ablation. However, this achievement was associated with an increase in the cost of the procedure.⁴⁷

Approach to the Difficult Cavotricuspid Isthmus Ablation

Although ablation of typical AFL is successful in more than 90% of cases, significant difficulties are occasionally encountered when attempting to terminate the flutter or create bidirectional conduction block across the CTI. In these instances, the first step is to reconfirm the diagnosis of CTI-dependent AFL by entrainment mapping on the septal, lateral, and middle portion of the isthmus. Once the diagnosis of typical AFL is verified, other potential contributors to failure of CTI ablation should be considered, including poor catheter contact, inadequate power delivery, thick myocardium, and discontinuous ablation line, typically caused by the presence of pouches, recesses, ridges, and trabeculations within the CTI. These factors can also be responsible for failure to produce bidirectional CTI block or for recovery of CTI conduction and recurrent AFL during follow-up after an acutely successful ablation.^{3,7,48}

Inadequate RF energy delivery. If a standard 4- or 5-mm-tip ablation catheter is used initially, ablation failure may be related to inadequate RF energy delivery. In this setting, RF ablation catheters with a large (8-mm) distal electrode and irrigated-tip catheters allow the creation of larger lesions in high- and low-flow regions. Importantly, local edema caused by a prior ineffective RF application can potentially form a barrier preventing deeper penetration of subsequent RF applications.

Failure to ablate across the entire isthmus. Not infrequently, the curvature of the ablation catheter does not enable the ablation electrode to reach the ventricular aspect of the CTI. In this setting, using preshaped or deflectable guiding sheaths can enable access of the ablation catheter to all locations across the CTI.

In addition, conducting gaps anywhere along the CTI can cause arrhythmia recurrence. Full mapping of the CTI is required to identify those gaps. Quite commonly, conduction recurs at the site at which block was first achieved, but can occur anywhere along the line. Widely separated double potentials indicate local block under the recording catheter bipole. Further ablation of these regions is not necessary. When double potentials separated by an isoelectric interval can be traced in a convergent configuration, with a progressively decreasing interpotential interval, and culminate in a fractionated continuous electrogram, this finding indicates a gap in the line of block, which should be selectively targeted by additional ablation. High-density electroanatomic mapping can be helpful in identifying the gaps in the ablation line.⁴⁹

Sub-eustachian pouches. When present, deep sub-eustachian pouches tend to be most prominent in the vestibular portion close to the septum and are typically associated with a prominent valve of Thebesius (which guards the CS os; see Fig. 12.15). The presence of a prominent sub-eustachian pouch can be suggested by a characteristic inferior dip of the catheter tip when the ablation catheter is dragged back across the isthmus toward the IVC. Catheter stability and power delivery for ablation within these pouches are frequently suboptimal, especially when eustachian ridge act as a fulcrum, preventing the catheter tip from falling into the pouch. Making a tight (180 degrees) curve on the ablation catheter within the RA (or using a preshaped “ramp” guiding sheath or a steerable sheath) and withdrawing the catheter can direct the tip vertically on the CTI (instead of the usual horizontal direction) and help position the ablation electrode deep within the pouch. Then small changes in the angle of catheter curvature enable delivery of contiguous ablation lesions across the floor of the pouch. Alternatively, performing ablation relatively more laterally on the CTI can circumvent the problems of power delivery and potential perforation when ablating within a pouch. If linear ablation more laterally is unsuccessful because of poor catheter stability or thick myocardium, irrigated-tip catheters can be of advantage; however, careful titration of energy delivery is necessary to avoid steam pops. When ablation is still unsuccessful, adequate visualization of the pouch (using RA angiography or phased-array intracardiac echocardiography) can be useful to guide ablation within or around the pouch.^{3,7,48}

Prominent pectinate muscles. Prominent pectinate muscles encroaching on the CTI can be suggested by the presence of sites with unusually high-voltage electrograms (from pectinate muscle ridges) surrounded by areas where abrupt impedance rises and minimal power delivery occurs (likely from poor blood flow in the crevices between pectinate muscles). The thickness of prominent pectinates can prevent transmural ablation lesions and hamper adequate catheter stability. In addition, the catheter tip can become wedged between the pectinate muscles with consequent inadequate power delivery with impedance rise, and coagulum formation may occur because of poor blood circulation. In these situations, performing ablation closer to the septum, where the pectinate muscles are usually less prominent, and using large-tip or irrigated-tip catheters can help achieve successful ablation.^{7,48}

Prominent eustachian ridge. A prominent eustachian ridge can hinder catheter manipulation to the septal aspect of the isthmus because the crest of the ridge can act as a fulcrum, directing the catheter tip laterally when clockwise torque is applied (instead of the expected medial rotation). In addition, when the eustachian ridge is prominent, electrode contact can be difficult to maintain on the upslope of the ridge (the portion between the crest of the eustachian ridge and the tricuspid

annulus). In these situations, the use of preshaped guiding sheaths (e.g., SRO, SL1, or Ramp sheath) often solves the problem.

Cryoablation

Cryothermal ablation utilizes a steerable 9 Fr, 8-mm-tip catheter (Freezor MAX, Medtronic CryoCath, Montreal, Canada). Cryoablation of the CTI is performed using a point-by-point sequential application technique from the TV annulus to the IVC. Each application lasted for 240 seconds, targeting a temperature of -80°C .

Although there is no reason to believe that cryothermal ablation will be more effective than RF ablation of the CTI, cryothermal ablation has the advantage of being less painful. Acute success rates are comparable to those for RF ablation. Data have been mixed, however, regarding long-term outcome after cryoablation. A recent report demonstrated comparable efficacy of cryoablation to RF ablation.⁵⁰ However, other studies found lesion durability from cryoablation to be significantly inferior to that of RF ablation, as evidenced by the higher recurrence rate of symptomatic AFL (11% vs. 0%) and even higher rates of asymptomatic recovery of CTI conduction (34% vs. 15%). In addition, compared with RF ablation, cryoablation is associated with significantly longer procedure times; this is driven mainly by differences in ablation duration, which can be attributed to the longer duration of each cryoablation (4 minutes) compared with RF ablation (up to 60 seconds).⁵¹

Endpoints of Ablation

Tachycardia Elimination

When ablation is performed during AFL, the first endpoint is to terminate the arrhythmia during RF energy delivery. After termination of AFL, programmed atrial stimulation is performed to evaluate inducibility of the arrhythmia. Importantly, the termination or noninducibility of AFL are often not associated with complete isthmus block and hence should not be considered a reliable ablation endpoint without confirmation of the presence of complete bidirectional CTI block. Without achieving CTI block, the substrate for AFL is left intact (even when AFL terminates during ablation) and hence the risk of arrhythmia recurrence is high.

Bidirectional Isthmus Block

Complete bidirectional CTI block is the primary endpoint of ablation of typical AFL. Several methods (Table 12.1) can be used to demonstrate the presence of bidirectional CTI block. However, the distinction between incomplete block with very slow conduction across the CTI versus complete CTI conduction block can be very difficult, even with detailed mapping. Therefore it is important to utilize multiple techniques to confirm the presence of CTI block.

Adenosine Challenge

Recovery of CTI conduction, likely related to nontransmural ablation lesions, is the most common mechanism for long-term recurrence of AFL after ablation. Acute recovery of CTI conduction can occur in more than 15% of patients within minutes to over 1 hour after initially successful ablation. Therefore reconfirmation of CTI block is repeated 30 minutes after the last RF application. Adenosine (12 to 18 mg IV bolus) and, to a lesser degree, isoproterenol infusion (titrated to increase baseline sinus rate by 50%) can help reveal dormant trans-isthmus conduction. In fact, adenosine challenge following AFL ablation was found to provoke transient (for as little as 1 or 2 beats, and usually for less than 1 minute) or persistent resumption of conduction across the CTI in up to 23% of patients. Adenosine-induced second- or third-degree AV block seemed to be a prerequisite for its effects on CTI conduction; therefore the dose of adenosine is increased gradually until second- or third-degree AV block occurs. Adenosine-induced “dormant

TABLE 12.1 Confirmation of Bidirectional Isthmus Block

Method	Technique	Observations Consistent With CTI Block
Atrial activation sequence during atrial pacing	Mapping inferolateral RA activation sequence during pacing from the CS os (at PCL of 600 msec)	Clockwise CTI block is indicated by the observation of a purely descending (craniocaudal) wavefront at the inferolateral wall down to the CTI (proximal-to-distal activation sequence on the Halo catheter positioned around the tricuspid annulus)
Atrial activation sequence during atrial pacing	Mapping septal RA activation sequence during pacing from the low lateral RA (at PCL of 600 msec)	Counterclockwise CTI block is indicated by the observation of a completely descending (craniocaudal) wavefront at the RA septum, with CS os activation occurring after activation of the high RA and the HB region
Transisthmus conduction interval	Measuring transisthmus conduction interval during pacing from CS os, then from low lateral RA pacing (Transisthmus interval equals the interval from the stimulus artifact from one side of the isthmus to the atrial electrogram recorded on the contralateral side)	Prolongation of transisthmus interval post ablation by >50% from baseline (or to an absolute value of ≥ 150 msec)
Double potentials	Mapping of double potentials along the entire CTI ablation line during pacing from either side of the CTI (CS os or low lateral RA, at PCL of 600 msec)	The presence complete corridor of widely spaced double potentials (separated by an interval of ≥ 110 msec) along the entire CTI ablation line
Differential pacing	Mapping of double potentials along the entire CTI ablation line during pacing from low lateral RA, then from midlateral RA (at PCL of 600 msec)	Separation between the double potentials is decreased upon moving the pacing site away from the ablation line (from low lateral to midlateral RA)
Differential pacing	Mapping activation at the CTI ablation line during pacing from low lateral RA, then from midlateral RA, or from CS os then RA septum (at PCL of 600 msec)	Moving the pacing site away from the ablation line (from low lateral to midlateral RA or from CS os to RA septum) shortens the conduction time to the contralateral side of the ablation line
Incremental pacing	Mapping of double potentials along the CTI ablation line during pacing from low lateral RA, then from CS os (at PCLs of 600 msec then 300 msec)	Minimal (<20 msec) variation in the distance between the double potentials in response to progressively faster pacing rates
Incremental pacing	Measuring the interval between atrial electrograms at the HB region and CS os (His-to-CS os interval) during pacing from low lateral RA (at PCLs of 600 msec then 300 msec)	Minimal (<10 msec) variation in the His-to-CS os interval in response to progressively faster pacing rates
Unipolar electrogram morphology	Recording unipolar electrograms at the CTI ablation line during pacing from either side of the CTI (CS os or low lateral RA, at PCL of 600 msec)	Unipolar electrogram recorded at the edge of the ablation line contralateral to the pacing site exhibits monophasic R or Rs wave (large positive deflection followed by a negative deflection with R/s ratio $>3:1$)
Bipolar electrogram morphology	Recording bipolar electrogram just lateral to the CTI ablation line during pacing from the CS os (at PCL of 600 msec)	Bipolar electrogram polarity reverses (as compared to preablation electrogram polarity)
Electroanatomic mapping	Electroanatomic mapping	Pacing from one side of the ablation line results in an activation wavefront propagating in one direction around the tricuspid annulus, with the latest activation in the CTI immediately on the contralateral side of the ablation line

CS os, Coronary sinus ostium; CTI, cavotricuspid isthmus; HB, His bundle; msec, milliseconds; PCL, pacing cycle length; RA, right atrium.

conduction” precedes early relapse of permanent conduction, and hence it can identify a subgroup of patients at higher risk of long-term arrhythmia recurrence. Patients without adenosine-mediated “dormant transisthmus conduction” immediately after CTI block has been demonstrated typically have no recovery of conduction during the postablation waiting period.^{52–54}

Confirmation of Bidirectional Cavotricuspid Isthmus Block

Atrial Activation Sequence During Atrial Pacing

Complete bidirectional CTI block is demonstrated by pacing from the CS os and RA lateral wall and observing that sequential atrial activation terminates at the ablation line, on the contralateral side from the pacing site.

Normally, during atrial pacing at a CL of 600 milliseconds from the CS os, one wavefront propagates from the CS pacing site in a clockwise direction through the CTI to the low lateral RA. The other wavefront

from the CS os ascends up the atrial septum to the high RA in a counterclockwise direction, with resulting collision of wavefronts at the upper part of the lateral RA (the exact location of wavefront collision depends on the relative conduction velocities of the RA and the CTI) and generating an atrial activation sequence with a chevron pattern (Figs. 12.17 and 12.18).

Clockwise CTI block is indicated by the observation of a purely descending wavefront at the lateral wall down to the CTI (proximal-to-distal activation sequence on the Halo catheter positioned around the tricuspid annulus) when pacing from the CS os (i.e., pacing of the septal side of the ablation line). This block is associated with marked prolongation of the CTI conduction duration (i.e., the interval from the CS os to the low lateral RA; see Fig. 12.17). Incomplete clockwise CTI block is said to occur when a descending wavefront at the lateral RA wall still allows the lateral part of the CTI to be activated from the CS os in a clockwise direction across the CTI but at a slower conduction velocity, resulting in displacement of collision of the clockwise and

Fig. 12.17 The Use of Coronary Sinus (CS) Pacing to Verify the Presence of Clockwise Cavotricuspid Isthmus (CTI) Block. *Upper panels*, Intracardiac recordings from the right atrium (RA), CS, and CTI. *Lower panels*, Left anterior oblique fluoroscopic view illustrating the position of the ablation catheter at the CTI, and the Halo catheter around the tricuspid annulus (TA), with the distal end at the lateral end of the CTI. When CTI conduction is intact (*left panel*), pacing from the CS ostium results in the collision of activation wavefronts in the lateral RA wall (*red and blue arrows*). *Middle panel*, The collision point moves toward the low lateral RA wall when incomplete block is present. *Right panel*, Complete clockwise CTI block is indicated by the observation of a purely descending wavefront at the lateral wall down to the CTI (proximal-to-distal Halo sequence). The bipolar electrogram recording from the CTI initially shows a single atrial potential (*left panel*, *gold arrow*). With partial CTI ablation, the atrial electrogram splits into two closely adjacent potentials (*middle panel*, *gold arrows*). Complete CTI block is indicated by the observation of double potentials separated by an isoelectric interval (*right panel*, *gold arrows*). In addition, bipolar electrogram polarity reversal (*left panel*) is observed in the distal Halo and the distal ablation electrode recordings when complete block is achieved (as compared with before complete CTI block is achieved in the *right and middle panels*), thus indicating reversal of the direction of the activation wavefront lateral to the line of block (*green and gold arrows*). Positive (R wave) morphology of the unipolar recording lateral to the line of block also indicates complete CTI block (in contrast to biphasic [RS] electrogram morphology when intact conduction or only incomplete block is present). ABL, Ablation site; CS_{dist}, distal coronary sinus; CS_{prox}, proximal coronary sinus; TA_{dist}, distal tricuspid annulus; TA_{prox}, proximal tricuspid annulus.

counterclockwise wavefronts to the lower part of lateral RA. The distal bipole of the Halo catheter (Halo 1-2) at the lateral part of the CTI is activated slightly before or at the same time as bipole Halo 3-4, situated more laterally (see [Figs. 12.17](#) and [12.18](#)).

Importantly, the correct positioning of the Halo catheter at the tricuspid annulus (with the tip of the catheter immediately lateral to the CTI ablation line) is essential for reliable analysis of the activation sequence in the lateral RA and verification of CTI block. Migration of parts of the Halo catheter posterior to the crista terminalis or posterior to the eustachian ridge can suggest incomplete CTI block

(pseudo-conduction) when complete CTI is actually present ([eFig. 12.6](#), [Fig. 12.19](#)). When stable positioning the tip of the Halo catheter in close proximity to the ablation line proves to be difficult, the tip of the ablation catheter can be positioned immediately lateral to the ablation line to complement the recordings obtained by the Halo catheter.

It is also important to recognize that monitoring only the atrial activation sequence of the RA lateral wall recorded by the Halo catheter during CS pacing can lead to diagnostic errors in a significant proportion of patients. This is because of the inability to detect very slow

eFig. 12.6 Effect of Poor Halo Catheter Positioning on Electrograms. In (A), despite extensive ablation (*Abl*) in the cavotricuspid isthmus (CTI), it appears that activation is still proceeding through the CTI to activate Halo electrodes 1–4 directly (*red arrows*). In (B), the electroanatomic map shows that the Halo catheter is incorrectly positioned posteriorly in the right atrium, such that tip electrodes are behind the eustachian ridge and recording the posterior right atrium rather than the CTI position. In (C) and (D), after repositioning the catheter from its prior posterior location to a more tricuspid annular position as indicated by presence of small ventricular electrograms (*blue arrows*, C) and visualized on the electroanatomic map (D), Halo electrode activation now suggests CTI block. CS, Coronary sinus; IVC, inferior vena cava; SVC, superior vena cava; TA, tricuspid annulus.

Fig. 12.18 Confirmation of Bidirectional Cavotricuspid Isthmus (CTI) Block Using Differential Pacing. Shown are figures of the right atrium, facing the tricuspid annulus (TA). A 20-pole electrode catheter is arrayed around the TA (dark blue), while another catheter is inside coronary sinus (CS, light blue). An asterisk (*) indicates stimulation site. Nine panels are shown, with pacing from the CS as well as two adjacent pairs of electrode on the TA catheter close to the CTI ablation line, in the baseline state (prior to ablation); in the setting of some ablation but with persistent slow conduction through the CTI; and finally with complete CTI block. Green arrows indicate directions of wavefront propagation from stimulation sites. IVC, Inferior vena cava; SVC, superior vena cava.

residual isthmus conduction that allows the wavefront propagating in an opposite direction to reach the ablation line before conduction through the isthmus is completed. Theoretically, slow but persistent isthmus conduction that can be confined within the ablation line or part of the isthmus distant from an area mapped by the multipolar catheter can therefore be misdiagnosed, no matter how closely the distal tip of the Halo catheter is placed to the ablation line, or even if the Halo catheter is positioned across the ablation line.

During low lateral RA pacing prior to ablation, the RA activation sequence (with intact counterclockwise CTI conduction) exhibits two ascending wavefronts (septal and lateral) leading to impulse collision at the high lateral wall. The caudocranial activation of the RA septum following counterclockwise propagation of the paced wavefront through the CTI results in atrial activation in the CS os preceding that in the HB region (Fig. 12.20, see also Fig. 12.18). Furthermore, intact conduction through the CTI permits the paced wavefront to proceed rapidly

to activate the LA from below (and CS activation propagates in a proximal-to-distal direction), thus giving rise to an inverted P wave in the inferior leads.

In contrast, during low lateral RA pacing, counterclockwise CTI block (or conduction delay) is indicated by the observation of a single ascending wavefront at the lateral wall (distal-to-proximal Halo sequence), followed by a completely descending wavefront at the septum to reach the CS os. Hence, compared with baseline, counterclockwise CTI block is associated with inversion of the direction of the septal activation from ascending to descending. Furthermore, the CS os electrogram is activated after the high RA and the HB region (see Figs. 12.18 and 12.20). In addition, counterclockwise conduction block in the CTI forces the wavefront to activate the LA from above via the Bachmann's bundle—and CS activation propagates in a distal-to-proximal direction—giving rise to a different P wave morphology, with the terminal portion positive in the inferior leads.

Fig. 12.19 Pseudo-Block and Pseudo-Conduction During Attempted Cavotricuspid Isthmus (CTI) Ablation. Shown are figures of the right atrium, facing the tricuspid annulus (TA) as shown. A 20-pole electrode catheter is arrayed around the TA (dark blue), while another catheter is inside coronary sinus (CS, light blue). An asterisk (*) indicates stimulation site. At left, the 20-pole TA catheter tip is far removed from the ablation line, where slow conduction can remain but not be evident since the wave front from the opposite direction reaches the distal TA electrodes first. This erroneously suggests the presence of CTI block, the solution for which is having recordings closer to the lateral aspect of the ablation line. At right, the TA catheter is positioned too posteriorly (not in CTI); a wave front of activation (dark green) can then proceed posterior to the inferior vena caval orifice to activate the distal TA electrodes first, suggesting persistent CTI conduction (when block is actually present). The solution for this is to position the TA catheter correctly.

Trans-Isthmus Conduction Interval

The trans-isthmus conduction interval is measured during CS os or low lateral RA pacing; it is equal to the interval from the stimulus artifact from one side of the isthmus to the atrial electrogram recorded on the contralateral side. Prolongation of this interval by more than 50% (or to an absolute value of 150 milliseconds or more) suggests CTI block (see Fig. 12.17). This criterion has sensitivity and negative predictive values of 100%. However, the specificity and positive predictive values are less than 90%.

Double Potentials

The demonstration of a continuous corridor of widely split double potentials recorded along the entire length of the ablation line confirms the presence of block. It is important to recognize that double potentials separated by long isoelectric intervals indicate “local block” under the recording catheter bipole, but they can be just adjacent to a conducting gap; therefore meticulous mapping of the entire length of the CTI ablation line is necessary to verify the presence of complete CTI block and to exclude the presence of gaps along the ablation line.⁴⁹

During atrial pacing from either side of the CTI (CS os or low lateral RA), the presence of continuous corridor of widely split double potentials (separated by a peak-to-peak interval of 110 milliseconds or more) along the entire CTI ablation line is the most accurate available indicator of complete CTI block, and generally considered the gold standard for determining complete bidirectional block (see Fig. 12.17). On the other hand, when the interval separating the double potentials is less than 90 milliseconds at any point along the ablation line, complete isthmus block is not confirmed, and the search for persistent conduction through a gap should be carried out. When there is a gap in a line of block, the

Fig. 12.20 The Use of Differential Pacing From the Lateral Right Atrial (RA) Wall to Verify the Presence of Counterclockwise Cavotricuspid Isthmus (CTI) Block. (A) Pacing from the lateral aspect of the CTI (Halo 1,2) before CTI ablation. (B to D) Pacing from different lateral RA sites along the Halo catheter after CTI ablation (B) pacing from Halo 3,4; (C) pacing from Halo 5,6; (D) pacing from Halo 7,8. When CTI conduction is intact, coronary sinus ostium (CS os) activation occurs via a counterclockwise wavefront across the CTI, and because the CS os is anatomically closer to the pacing site than the His bundle (HB), atrial activation in the CS os electrode precedes that in the HB electrode. In the presence of counterclockwise CTI block, CS os activation occurs via the wavefront propagating in a clockwise direction up the RA lateral wall, over the RA roof, and then down the septum. Consequently, CS os activation (as measured by the stimulus-to-local electrogram interval) occurs progressively earlier during pacing from more cephalic sites along the lateral RA wall (B to D). In addition, activation of the CS os occurs after the high RA and the HB region. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; TA_{dist}, distal tricuspid annulus; TA_{prox}, proximal tricuspid annulus.

isoelectric interval between the double potentials shortens the closer the electrograms are to the gap. At the gap, in the line of block, double potentials are no longer present, and the electrogram is typically long and fractionated, but can also be discrete. Those gaps are then targeted by additional ablation until complete CTI block is achieved.

This technique requires meticulous mapping of the CTI, and is probably more difficult to perform than the classic activation mapping technique, mainly because of the ambiguity of electrogram interpretation (e.g., multiple, low amplitude, or fragmented potentials) along the ablation line, especially after extensive ablation attempt or broad or nonlinear ablation of the CTI. When double potentials cannot be visualized, the interval between the pair of electrograms immediately on either side of the line of block (the DP + 1 interval), when pacing immediately medial and lateral to the line of block, can be used as an alternative method for verifying complete bidirectional CTI block. This technique requires positioning of a duodecapolar catheter around the tricuspid annulus while extending the catheter tip inside the CS, so that the catheter straddles the CTI and provides recording and pacing from the medial and lateral aspects of the isthmus. The DP + 1 interval cutoff of 140 milliseconds seems to have better or equal sensitivity, specificity, and positive predictive values as compared to other criteria for confirming the presence of CTI block. Nevertheless, it is still very difficult to distinguish incomplete block with very slow conduction from complete isthmus block. In addition, gaps along the ablation line

remote from the duodecapolar catheter would result in a DP + 1 interval that is long in the absence of complete CTI block.⁵²

Differential Pacing

This technique is used to verify whether the double potentials recorded at the ablation line are secondary to complete line of block or the result of slow conduction across the ablation line. Fixed-rate pacing is performed from the low lateral and midlateral RA. With intact CTI conduction, both components of the recorded electrogram (the double potentials) are the result of sequential activation by the same paced wavefront propagating in a counterclockwise direction across the CTI (the two components are linked to the same counterclockwise wavefront). Therefore withdrawal of the pacing site farther away from the ablation line (from low lateral RA to midlateral RA) causes a similar degree of delay of the timing of both components of the electrogram (relative to the pacing stimulus), so that the interval between the double potentials remains constant (Fig. 12.21).

On the other hand, when complete CTI block is present, the first component of the double potentials (at the lateral aspect of the ablation line) reflects activation by the paced wavefront traveling counterclockwise from the nearby pacing site, whereas the second component of the double potential (at the medial aspect of the ablation line) is the result of activation by the wavefront traveling in the opposite direction (clockwise) around the tricuspid annulus. Hence the two components

Fig. 12.21 Confirmation of Bidirectional Cavotricuspid Isthmus (CTI) Block Using Distance Between Double Potentials in the Region of the Ablation Line. Shown are figures of the right atrium, facing the tricuspid annulus (TA) as shown. A 20-pole electrode catheter is arrayed around the TA (dark blue). An asterisk (*) indicates stimulation site. At top, wavefronts of activation are shown in three different states (baseline, with partial CTI block, and complete CTI block) when pacing from electrodes 5 and 6; bottom panels show similar findings with pacing from electrodes 7 and 8. As can be seen, split potentials develop during partial ablation, and have the same spacing (95 milliseconds) regardless of which electrodes are paced (although the timing from stimulus to the first of the split potentials occurs later when pacing from a more lateral site). With complete block, the separation of split potentials is widest when pacing closer to the ablation line.

are not linked to a single wavefront; rather they can be dissociated from each other by changing the activation wavefront. As a consequence, withdrawal of the pacing site farther away from the ablation line (from low lateral RA to midlateral RA) results in a delay of the first component of the double potentials, but the second component of the double potentials becomes activated earlier (hence separation of double potentials decreases), since the length of the detour the clockwise wavefront has to travel is shortened by the new (midlateral RA) site of pacing (eFig. 12.7).

Using a similar principle, the local activation time at the CS os electrode during fixed-rate pacing performed from the low lateral and midlateral RA can be used for evaluation of counterclockwise CTI block. Normally (with intact isthmus conduction) CS os activation occurs via propagation of the paced wavefront across the CTI in a counterclockwise direction. Therefore CS os activation occurs earlier during pacing from the low lateral RA compared with the midlateral RA because the low lateral RA is anatomically closer to the CS os. In contrast, when counterclockwise CTI block is present, CS os activation occurs via the wavefront propagating in a clockwise direction around the tricuspid annulus (see Figs. 12.18 and 12.20). Consequently, CS os activation occurs earlier during pacing from the midlateral compared with the low lateral RA, because the length of the detour is shortened by pacing from the midlateral RA.

Incremental Pacing

Incomplete block can be associated with very slow conduction across the CTI, mimicking the activation pattern related to complete block. The incremental pacing maneuver helps distinguish isthmus block from long local conduction delay across the isthmus based on the observation that residual CTI conduction is usually decremental and is worsened at faster pacing rates.

Initially the mapping catheter is used to record double potentials along the CTI ablation line. The catheter is then placed at the site registering the maximum separation between the two potentials (as measured by the “peak-to-peak” distance between them). Then, incremental pacing is performed at either side of the CTI (CS os and the low lateral RA) at PCLs of 600 and 300 milliseconds, and the maximal separation between the double potentials is measured at each PCL.⁵⁵

Minimal (less than 20 milliseconds) variation in the distance between the double potentials in response to progressively faster (from 600 milliseconds to 300 milliseconds) pacing is consistent with complete block across the ablation line. Such observation during CS os pacing indicates complete clockwise isthmus block, and during low lateral RA pacing indicates counterclockwise complete CTI conduction block. On the other hand, prolongation of the interval between separating the double potentials by more than 20 milliseconds at the faster pacing rate suggests persistent residual conduction across the isthmus or CTI functional block.^{55,56}

A variation of this technique evaluates the effect of incremental pacing from the low lateral RA on the interval between atrial activation of the HB region and that at the CS os (His-to-CS os interval). The lack of increase in His-to-CS os atrial interval (variation of less than 10 milliseconds) in response during incremental pacing from the low lateral RA is consistent with complete counterclockwise CTI block, whereas a more than 10 millisecond increase of the His-to-CS os atrial interval with incremental pacing suggests slow conduction and functional block across the CTI. An advantage of the incremental His-to-CS os maneuver is that it does not require the identification of double potentials along the CTI ablation line, which can occasionally be difficult to record.⁵⁷

Another variation employs the effect of incremental pacing from the CS os on atrial activation sequence in the low lateral RA to evaluate

clockwise CTI block. With incomplete CTI block, activation of the low lateral RA during CS os pacing can be delayed, but activation can still occur via the CTI (in a clockwise direction) at the same time or just earlier than the wavefront traveling to the low lateral RA from the counterclockwise direction around the tricuspid annulus. Increasing the pacing rate results in decremental conduction across the now diseased isthmus and causes further delay in activation of the low lateral RA (eFig. 12.8). In contrast, when complete CTI block is present, the lateral RA is activated in a counterclockwise direction across the atrial septum and RA roof. Because these atrial regions conduct nondecrementally, pacing at faster rates should not change the timing of low lateral RA activation significantly, as long as the PCL is longer than atrial refractoriness.

Unipolar Electrogram Morphology

The morphology of the unfiltered unipolar recording indicates the direction of wavefront propagation. Positive deflections (R waves) are generated by propagation toward the recording electrode; negative deflections (QS complexes) are generated by propagation away from the electrode. Conduction along the longitudinal axis of the fibers in cardiac muscle produces a characteristic biphasic (RS or rS) unipolar electrogram. In contrast, positive uniphasic (R) unipolar electrograms are characteristic of the end of propagation of the activation wavefront. Uniphasic (R) unipolar electrograms can also be observed at the point of collision of two wavefronts, and negative waveforms (QS) are recorded in the vicinity of the site of excitation onset.

With intact CTI conduction (before ablation), pacing from either side of the CTI results in an RS, rS, or QS pattern on the opposite side of the CTI. A terminal S wave in the unipolar electrogram is expected, because the propagated wavefront propagates through the CTI and moves away from the mapping electrode. In addition, because atrial depolarization along the CTI occurs sequentially in the same direction, the polarity of the initial depolarization is the same from each pair of recording electrodes when using unfiltered unipolar recording on the CTI. A similar pattern is also observed in the presence of incomplete CTI block (after failed CTI ablation). Because unipolar electrograms record relatively distant activity, they are able to detect slow conduction through the CTI independently of the location of the gap, since the wavefront crossing the CTI (sometimes with a prolonged conduction time) has to pass through the mapping electrode, generating a propagation wavefront that moves away from the recording site and hence a terminal S wave.^{58,59}

After CTI block is achieved, the paced wavefront has to travel around the tricuspid annulus before it reaches the mapping electrode, located at the contralateral side of the line of block. Therefore a clear change in the unipolar electrogram is expected (from QS, rS, or RS to R or Rs) because the wavefront now ends at or close to the exploring electrode (see Fig. 12.17). The relative voltage of the R wave is likely to depend on the amount of tissue that depolarizes within the CTI, as well as the distance of the recording electrode from this area.^{58,59}

Importantly, to observe the expected change in the morphology of unipolar electrograms, the exploring catheter should be located in close proximity to the line of block. If the exploring catheter is separated from the line of block, activation of the area of tissue between the exploring electrode and the line of block can potentially generate an S wave of sufficient voltage to result in an RS unipolar electrogram.⁵⁸

Bipolar Electrogram Polarity

Bipolar recordings predominantly reflect local activation time; signal subtraction used to create a bipolar signal largely eliminates morphology information at either electrode. Nonetheless, the polarity of the bipolar electrogram is sensitive to the direction of wavefront propagation from

eFig. 12.7 Differential Pacing for Verification of Complete Line of Block. Fixed-rate pacing (S1) is performed from the at lateral aspect of the CT1 (A), low lateral RA (B), and midlateral RA (C) via the Halo catheter placed around the tricuspid annulus with the distal tip (TA_{dist}) positioned just lateral to the CTI. Double potentials (P1 and P2) are recorded on the distal ablation electrode (ABL_{dist}) positioned at the CTI ablation line. Withdrawal of the pacing site farther away from the ablation line (from panel A to B to C) results in a delay of the first component (P1, red arrows) of the double potentials, but the second component (P2, blue arrows) of the double potentials becomes activated earlier (hence separation of double potentials decreases). This is consistent with counterclockwise block across the CTI ablation line, whereby the first component of the double potentials (at the lateral aspect of the ablation line) reflects activation by the paced wavefront traveling counterclockwise from the nearby pacing site; while the second component of the double potential (at the medial aspect of the ablation line) is the result of activation by the wavefront traveling in the opposite direction (clockwise) around the tricuspid annulus. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; TA_{prox}, proximal tricuspid annulus; V, ventricular electrogram.

eFig. 12.8 Surface Electrocardiogram and Intracardiac Recordings Following Incomplete Ablation of the Cavotricuspid Isthmus (CTI). The activation sequence around the tricuspid annulus during coronary sinus pacing at a cycle length of 600 milliseconds (*blue S1*) suggests block in the CTI (*blue arrow*); however, pacing at a shorter cycle length (300 milliseconds, *red S1*) causes more delay of activation timing (*red arrow*) of the most distal tricuspid annulus electrodes (at the lateral aspect of the CTI) and thus reveals that conduction had been present in the CTI at the slower paced rate. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; TA_{dist}, distal tricuspid annulus; TA_{prox}, proximal tricuspid annulus.

Fig. 12.22 Confirmation of Bidirectional Cavotricuspid Isthmus (CTI) Block Using Change in Bipolar Electrogram Polarity on Opposite Sides of the Ablation Line. Shown are figures of the right atrium, facing the tricuspid annulus (TA) as shown. A 20-pole electrode catheter is arrayed around the TA (dark blue), while another catheter is inside coronary sinus (CS, light blue). An asterisk (*) indicates stimulation site. Individual electrodes on the TA catheter are numbered. The baseline state, pacing from the CS shows the propagation from distal to proximal (electrodes 1–8) on the TA catheter. Each bipolar electrogram has an “Rs” configuration. After some ablation, but with residual conduction through the CTI, electrograms indicating trepidation in the same direction as in the prior panel remain “Rs,” while at electrodes 7–8, trepidation is in the opposite direction, yielding a “qR” configuration. At right, with complete CTI block, propagation has been reversed and electrodes 3–8, each pair of which now shows a qR pattern.

the distal to the proximal poles (cathode to anode). Reversal of the bipolar electrogram polarity can indicate a reversed wavefront direction. This characteristic can be used for verification of the presence of CTI block. A multipolar Halo catheter with short (2 mm) interelectrode spacing is used to map the isthmus. Bipolar electrograms are recorded with the distal electrode serving as the cathode. During CS os pacing, the activation wavefront propagates in a clockwise direction across the CTI, resulting in positive electrogram polarity at the Halo bipole positioned just lateral to an ablation line and parallel to the inferior aspect of the tricuspid annulus. Once complete CTI block is achieved, distal Halo bipole is activated only from the counterclockwise direction, resulting in reversal of electrogram polarity from positive to negative during CS os pacing (Fig. 12.22, see also Fig. 12.17). Importantly, the use of changes in electrogram polarity as an accurate indicator of complete isthmus block requires that the recording electrodes be positioned parallel to the direction of the depolarization wavefronts in the isthmus. If the orientation of the electrodes is somewhat oblique to the direction of the depolarization wavefront, or if the depolarization wavefront progresses across the isthmus in a fashion that is not entirely linear, the initial polarity of an electrogram recorded in the isthmus may not be in the same direction as the predominant polarity of the electrogram.

Electroanatomic Mapping

Electroanatomic 3-D activation mapping can be used to verify CTI block. When clockwise block in the CTI is achieved, proximal CS pacing results in an activation wavefront propagating in a counterclockwise fashion, with the latest activation in the CTI immediately lateral to the ablation line (eFig. 12.9). When conduction across the CTI is still intact, CS pacing produces an activation wavefront that propagates rapidly through the CTI, with the anterolateral RA wall activated last. Similar maps can be generated during low lateral RA pacing to confirm counterclockwise block in the CTI. Activation maps can also be evaluated for the presence of gaps in the ablation lines, as indicated by the early

breakthroughs from the ablation line (Fig. 12.23). However, following CTI ablation, the local electrograms at the ablation line can be complex—with double, triple, or fragmented potentials and unclear local activation time—and electroanatomic activation mapping can be challenging.

Outcome

The inability to create complete CTI block and successfully eliminate typical AFL is unusual in contemporary practice. In a meta-analysis of 158 studies, the overall acute success rate for AFL ablation was 93% for large-tip (8 to 10 mm) or irrigated ablation catheters, and 88% for 4- to 6-mm tip catheters. AFL recurrence rates were significantly reduced by use of large tip or irrigated catheters (7% vs. 14%) and by use of bidirectional CTI block as a procedural endpoint (9% vs. 24%).⁶⁰

For patients in whom typical AFL recurs after ablation, conduction through the CTI is usually responsible. Presumably, such recurrences reflect a failure to achieve bidirectional CTI block during the initial procedure, incorrect initial assessment of bidirectional block, or resumption of conduction across an initially blocked isthmus. The use of the more stringent endpoint of bidirectional CTI block significantly reduces the AFL recurrence rate. The incidence of AFL recurrence does not increase beyond 1 to 6 months of follow-up, a finding suggesting that if recovery of isthmus conduction is going to occur, it will have done so by 6 months.⁶⁰

The overall incidence of complications associated with AFL ablation is 3.2%. The most common are cardiovascular complications. Serious complications are rare (0.4%) and include AV block (most common, 0.2%), cardiac tamponade, transient inferior ST segment elevation or acute occlusion of the right coronary artery, and thromboembolic complications.^{60–62}

Following AFL ablation, AF can develop in approximately 20% to 30% (with short-term follow-up, approximately 1 year) and in up to 82% (with long-term follow-up, approximately 4 years) of patients with or without a prior history of AF. It appears that AFL is often an early

Fig. 12.9 Electroanatomic Mapping for Verification of Cavotricuspid Isthmus (CTI) Block. Left anterior oblique (A and C) and inferior (B and D) views of three-dimensional electroanatomic (CARTO) activation map of the right atrium during atrial pacing. (A and B) During pacing at a site (white dot) medial to the CTI ablation line, complete CTI block in the clockwise direction is indicated by the absence of activation proceeding through the ablation line (red dots); progression of color (from red to purple) indicates that activation of the entire tricuspid annulus (TA) remains counterclockwise, except for the small portion that is situated between the pacing site and the line of block. (C and D) During pacing at a site lateral to the CTI ablation line, complete CTI block in the counterclockwise direction is indicated by the absence of activation proceeding through the ablation line (red dots) and activation of the entire TA in a clockwise direction. IVC, Inferior vena cava.

Fig. 12.23 Electroanatomic Mapping of Gaps in the Cavotricuspid Isthmus (CTI) Ablation Line. Inferior views of three-dimension electroanatomic (Rhythmia) activation map of the right atrium and CTI. (A) Activation map is acquired during counterclockwise typical atrial flutter (AFL). Radiofrequency (RF) ablation (*white dots*) across the CTI resulted in termination of AFL. (B) Activation map is acquired during atrial pacing at medial (septal) aspect of the CTI ablation line. An early breakthrough activation (*arrow*) is visualized, indicating a gap in the ablation line. (C) Additional RF ablation is performed at the gap, and activation remapping is performed during pacing at the medial aspect of the CTI ablation line; complete CTI block in the counterclockwise direction is indicated by the absence of activation proceeding through the ablation line. CS, Coronary sinus; IVC, inferior vena cava; TA, tricuspid annulus.

marker of atrial electrical disease that frequently progresses to AF even after curative treatment for AFL. It is well established that CTI is not the cause of typical AFL, and while ablation of the CTI eliminates the AFL, it does not modify atrial remodeling and other pathogenic factors that predisposed to the development of AFL. Hence it should not be surprising that the persistence of those pathogenic factors, which are shared by both AF and AFL, would eventually precipitate AF.

In a meta-analysis, over an average follow-up of 16 months, AF occurred in 23% of patients with no preablation history of AF and in 53% of patients with a history of AF, despite successful AFL ablation. The incidence of AF increased over time in both groups; however, 5 years after ablation, the incidence of AF was similar in those with and without AF before ablation. Antiarrhythmic drug use after ablation was 32%. The long-term use of oral anticoagulation was 66%.⁶⁰ This finding has serious implications for patient selection, long-term arrhythmia-free success rates, postprocedure antiarrhythmic drug use, and long-term anticoagulation. Because AF predating ablation of AFL is very likely to recur, thus limiting the ability to discontinue antiarrhythmic medications or anticoagulation in many patients, the potential benefits of ablation of only AFL should be seriously scrutinized. Nevertheless, since AFL is frequently associated with faster ventricular rates than can be more difficult to control, and hence more severe symptoms than the episodes of AF, catheter ablation of AFL can offer symptomatic relief and improved quality of life in a portion of patients with both AF and AFL, when the AFL is the dominant and more clinically significant arrhythmia. Furthermore, a recent retrospective study found that patients with AFL undergoing CTI ablation (37% also had a history of AF) had a lower risk of systemic thromboembolic events and overall mortality, whether or not a history of AF is present.⁶³

Video 12.1. Ablation of the Cavotricuspid Isthmus Guided by Fluoroscopy. Fluoroscopic images are shown in the RAO and LAO projections during catheter ablation of the CTI in a patient with previous mechanical mitral valve replacement and tricuspid annuloplasty. A multipolar (“halo”) catheter is positioned around the tricuspid annulus and a decapolar catheter in the CS. The ablation catheter is advanced to the right ventricle under fluoroscopy (RAO view); the tip is deflected to achieve contact with the RV inferior wall and withdrawn progressively until the electrogram shows small atrial and large ventricular electrograms. The distal tip of the ablation catheter is then adjusted under fluoroscopy on the CTI in the LAO view until it is midway between the atrial septum and right atrial lateral wall (pointing toward 6 o’clock in a 60-degree LAO view). The catheter is then dragged across the CTI until it reaches the inferior vena cava (as evidenced by drop of the catheter tip at the end of the movie). A preshaped guiding sheath (ramp sheath) is used in this case to help extend the reach of the catheter tip and stabilize its position on the CTI. *AbI*, Ablation catheter; *CS*, coronary sinus; *CTI*, cavotricuspid isthmus; *LAO*, left anterior oblique; *MA*, mitral annulus; *RAO*, right anterior oblique; *TA*, tricuspid annulus.

Video 12.2 Confirmation of Conduction Block Across the Cavotricuspid Isthmus: CARTO Mapping During Atrial Pacing. Electroanatomic (CARTO 3) activation and propagation maps of the right atrium during typical counterclockwise atrial flutter and during atrial pacing after successful ablation of the cavotricuspid isthmus (CTI). Activation mapping is performed during pacing at the medial and then the lateral aspects of the CTI ablation line to confirm presence of complete bidirectional isthmus block. During pacing at a site medial to the CTI ablation line, complete CTI block in the clockwise direction is indicated by the absence of activation proceeding through the ablation line; progression of color (from red to purple) indicates that activation of the entire tricuspid annulus (TA) remains counterclockwise, except for the small portion that is situated between the pacing site and the line of block. During pacing at a site lateral to the CTI ablation line, complete CTI block in the counterclockwise direction is indicated by the absence of activation proceeding through the ablation line and activation of the entire TA in a clockwise direction. *IVC*, Inferior vena cava; *SVC*, superior vena cava.

Video 12.3. Catheter Ablation of the Cavotricuspid Isthmus. Guided by Rhythmia Mapping System. Electroanatomic (Rhythmia) activation and propagation maps of the right atrium is performed during typical counterclockwise atrial flutter. Then, radiofrequency (RF) ablation of the cavotricuspid isthmus (CTI) is performed and results in tachycardia termination. Note that the flutter terminates before complete isthmus ablation. *SVC*, Superior vena cava; *TA*, tricuspid annulus.

Video 12.4. Catheter Ablation of the Cavotricuspid Isthmus. Mapping gaps in the ablation line. Electroanatomic (Rhythmia) activation and propagation maps of the right atrium is performed during typical counterclockwise atrial flutter. Radiofrequency (RF) ablation of the cavotricuspid isthmus (CTI) is performed and successfully terminated the tachycardia. Electroanatomic activation mapping on both sides of the ablation line is performed (using the mini-basket catheter) during atrial pacing to confirm the presence of complete CTI block. Initially, during pacing from the proximal coronary sinus (CS), activation mapping revealed a conduction gap in the CTI ablation line. Additional RF ablation at the gap is performed and repeat activation mapping reveals complete block across the CTI ablation line. *IVC*, Inferior vena cava; *SVC*, superior vena cava; *TA*, tricuspid annulus.

PATHOPHYSIOLOGY

Organized atrial tachycardias (ATs) are broadly categorized as focal (centrifugal activation originating from a discrete site that incorporates automaticity, triggered activity, and microreentrant mechanisms) or macroreentrant (a relatively large reentrant circuit around a central obstacle).¹ Depending on whether the cavotricuspid isthmus (CTI) is critical to the reentry circuit, macroreentrant atrial tachycardias (MRATs) are divided into two groups: “CTI-dependent” MRAT or “non-CTI-dependent” MRAT (see Table 11.1).

CTI-dependent MRATs include typical atrial flutter (AFL), lower loop reentry, and intra-isthmus reentry. The term “atrial flutter” has traditionally been used to refer to a continuously waving pattern on the electrocardiogram (ECG), without an isoelectric baseline in at least one lead, whatever the cycle length (CL). “Typical AF” is reserved for a macroreentrant circuit with the activation wavefront rotating clockwise or counterclockwise around the tricuspid annulus and using the CTI as an essential part of the reentry circuit. “Atypical AFL” is simply a descriptive term for an AT with an ECG pattern of continuous undulation of the atrial complex, different from that in typical AFL. However, the term “atypical AFL” introduces unnecessary confusion, and a mechanistic description of the AT circuit in relation to atrial anatomy is preferred (e.g., perimitral macroreentry, lesional right atrial [RA] macroreentry).^{1,2}

Macroreentry

The mechanism of MRAT is reentrant activation around a large central obstacle, generally several centimeters in diameter, in at least one of its dimensions. The central obstacle can consist of normal or abnormal structures, and can be fixed, functional, or a combination of both. There is no single point of origin of activation, and atrial tissues outside the

circuit are activated from various parts of the circuit. The CL of MRAT can vary widely and is not a reliable predictor of the mechanism. When the mechanism of MRAT can be further elucidated through different mapping techniques, description of MRAT mechanisms must be made in relation to atrial anatomy, including a detailed description of the obstacles or boundaries of the circuit and the critical isthmuses.¹

Dual-Loop Reentry

Although MRAT can manifest as an isolated arrhythmia (*single-loop reentry*), it can also occur in conjunction with other reentry circuits (e.g., incisional MRAT and typical AFL). When two atrial macroreentrant circuits coexist and use neighboring anatomical structures, they create the so-called dual-loop reentry. The multiple loops can be engaged simultaneously or encountered sequentially. Not uncommonly, ablation of one tachycardia results in transition to the other; hence, ablation of both circuits is necessary for clinical success.

A figure-eight reentry is a specific type of dual-loop reentry involving two simultaneously coexisting loops with opposite directions of propagation and sharing a common segment of unidirectional activation.

Localized Reentry

The term *localized reentry* has been used to refer to a reentrant circuit that is localized to a small area (covering a surface diameter of <3 cm) and does not have a central obstacle. These circuits typically form in close proximity to scars or prior ablation lines, where severe local conduction abnormalities allow for very slow conduction to support perpetuation of reentry in such a small anatomical path. Typically, low-amplitude, long, fractionated electrograms occupying more than 70% of the tachycardia cycle length (TCL) can be recorded in a small region of the atrium, from which activation spreads out centrifugally to activate the rest of the atrium (Fig. 13.1). Hence, these localized reentry circuits can

mimic focal AT, especially if a limited number of endocardial recordings are collected. Although localized reentry circuits are much smaller than macroreentry circuits, they are still significantly larger than focal “microreentrant” AT, whose site of origin cannot be mapped spatially beyond a single point or a few adjacent points with the resolution of a standard 4-mm-tip catheter.

Cavotricuspid Isthmus-Dependent Right Atrial Macroreentry

Lower loop reentry and intra-isthmus reentry are macroreentrant circuits that are confined to the RA and incorporate the CTI as a critical part of the circuit. However, in contrast to typical AFL, the circuit is not peritricuspid (Fig. 13.2). Nevertheless, because the CTI is still a

necessary part of the circuit, these arrhythmias are amenable to CTI ablation, as is true for patients with typical AFL.^{1,3}

Lower Loop Reentry

Lower loop reentry is a form of CTI-dependent MRAT with a reentrant circuit around the inferior vena cava (IVC); therefore it is confined to the lower part of the RA (see Fig. 13.2). The activation wavefront can rotate around the IVC in a counterclockwise (i.e., the impulse travels within the CTI in a medial-to-lateral direction) or clockwise fashion. A breakdown in the inferoposterior boundaries of the CTI produced by the eustachian ridge and lower crista terminalis causes the circuit to revolve around the IVC (instead of around the tricuspid annulus), across the eustachian ridge, and through the crista terminalis, with slow

Fig. 13.2 Anatomy of Cavotricuspid-Dependent Atrial Flutter Circuits. *Top, center*, The right atrium is viewed from the right lateral aspect, with the lateral wall semitransparent. The cavotricuspid isthmus is shaded orange. (A) Counterclockwise flutter circuit. (B) Clockwise flutter circuit. (C) Lower loop reentry circuit. (D) Intra-isthmus reentry circuit. See text for discussion. Os, Ostium.

conduction because of transverse activation through that structure. Alternatively, the circuit can exit at the apex of the triangle of Koch and come behind the eustachian ridge to break through across the crista terminalis behind the IVC and then return to the CTI.³

Lower loop reentry often coexists with counterclockwise or clockwise typical AFL and is usually transient and terminates by itself or converts spontaneously into AFL or atrial fibrillation (AF).

Intra-Isthmus Reentry

Intra-isthmus reentry is a reentrant circuit usually occurring within the region bounded by the medial CTI and coronary sinus ostium (CS os) (see Fig. 13.2). Circuits in the mid and lateral portion of the CTI can also occur but are less common.⁴

This arrhythmia can be sustained and usually occurs in patients who have undergone prior, and often extensive, ablation at the CTI. Catheter ablation can result in islands of scarred areas and slowly conducting channels that can potentially provide the substrate for this arrhythmia. In one report, intra-isthmus reentry accounted for 21% of cases of “recurrent” AFL following prior successful CTI ablation. Of note, persistence of bidirectional CTI block following ablation of typical AFL does not exclude the possibility of intra-isthmus reentry, since the reentry circuit can exist medial to the line of CTI block. The reentry circuit can be quite small; fractionated potentials spanning one- to two-thirds of the TCL are typically recorded within the CTI.⁴

The atrial activation sequence around the tricuspid annulus electrograms can exhibit spontaneous or pacing-induced shifts from a counterclockwise to clockwise or fusion patterns. In addition, entrainment mapping from the lateral CTI demonstrates a postpacing interval (PPI) longer than the TCL, a finding indicating that the lateral CTI is not part of the reentrant circuit. On the other hand, pacing from the region of the medial CTI or CS os demonstrates concealed entrainment with a PPI equal to the TCL. Linear ablation across the medial CTI, usually at the site of a very prolonged electrogram, can eliminate the tachycardia.⁴

Non-CTI-Dependent Right Atrial Macroreentry

Incisional Right Atrial Macroreentry

Incisional or scar-mediated RA macroreentry circuits are the most common form of non-CTI-dependent RA MRATs. The incision on the RA free wall is a routine access site for corrective surgery for congenital or acquired heart disease. The atriotomy scar, suture lines, and cannulation sites form fixed obstacles that can potentially promote reentry by providing multiple protected isthmuses along with natural conduction barriers (such as valve annuli and caval ostia) and regions of atrial scarring caused by the underlying heart disease. In its simplest form, incisional RA MRAT uses a circuit that rotates around the atriotomy scar, with the lower turning point located between the end of the scar and the IVC, and the upper turning point located between the upper end of the scar or the superior vena cava (SVC). Other obstacles can also be included in the reentry circuit, such as anatomical structures located in the vicinity of the scar (e.g., SVC or IVC) or functional obstacles (anisotropic conduction delay or block).³

These patients often exhibit multiple clinical or inducible tachycardias, particularly typical AFL, indicating the complexity of the atrial substrate. Importantly, the atriotomy scar in the lateral or posterolateral RA forms a fixed posterior barrier to conduction in the superoinferior direction between the venae cavae, and a lateral boundary necessary for the development of a peritricuspid macroreentry (typical AFL) by preventing short-circuiting of the tricuspid annulus via the posterior atrium. This explains why typical AFL is the most common AT in this

patient population, accounting for more than 70% of all MRATs. Other RA MRATs involving free-wall atriotomy become progressively more common with more extensive atrial incisions.⁵

RA free-wall atriotomy is also widely used to access the left atrium (LA) for surgical replacement of the mitral valve. In fact, RA MRATs are more common than LA macroreentry in this group of patients. Other approaches for mitral valve surgeries involve incisions through the interatrial (Waterston) groove, transeptal incisions, and the superior transeptal approach. The latter surgical approach involves an extensive series of incisions in the lateral and superior RA, the interatrial septum, and the LA roof. Consequently, the superior transeptal approach has been associated with a higher risk of RA MRATs.⁶

Patients with congenital heart disease have a high prevalence of MRAT, particularly after they have undergone reparative or palliative surgical procedures. For MRATs in adults with repaired congenital heart disease, three RA circuits are generally identified: (1) lateral wall circuits with reentry around or related to the lateral atriotomy scar; (2) septal circuits with reentry around an atrial septal prosthetic patch (when present); and (3) typical AFL circuits using the CTI. These arrhythmias are discussed separately in Chapter 14.³

Right Atrial Macroreentry in the Absence of Previous Surgery

Rarely, RA MRATs have been observed in patients without prior surgery in whom the central obstacle is a large area of abnormal atrial myocardium and electrically silent zones, indicating scarring. The mechanism of atrial scarring remains uncertain, but it has been suggested that these low-voltage areas may reflect areas of fibrosis potentially related to inflammatory, infiltrative, or ischemic processes. These patients frequently exhibit multiple clinical or inducible tachycardias. The most common circuit involves macroreentry around the RA free wall, but the vast majority of these patients also have clinical or inducible typical AFL, and many had prior CTI ablation. The electrically silent area forms a fixed posterior conduction barrier, which likely facilitates the development of peritricuspid reentry.⁷

Upper Loop Reentry

This type of MRAT involves the upper portion of the RA, with transverse conduction across the crista terminalis and wavefront collision occurring at a lower part of the RA or within the CTI. The central obstacle of the circuit is composed of the crista terminalis (functional) and the SVC (fixed). The impulse rotating in the circuit can be in a counterclockwise or clockwise direction. The CTI is not an intrinsic part of the reentrant circuit. The lower turnaround point for this circuit is by conduction through a gap in functional block in the crista terminalis. Ablation of this gap can abolish the arrhythmia.⁸ Upper loop reentry can exist as a single loop or as a part of a dual-loop (figure-eight) reentry with lower-loop or with free-wall circuits.

Left Atrial Macroreentry

LA MRATs are frequently related to or coexist with AF. Areas of scar and low-voltage zones, associated with local conduction slowing or block, frequently promote the development of MRAT. Scar areas can be a result of previous atriotomy, surgical or catheter ablation, or can be spontaneous, producing electrically silent areas in the atrium.

Incisional Left Atrial Macroreentry

A variety of incisional LA macroreentry circuits have been described in patients with prior cardiac surgery involving the LA or atrial septum. The atriotomy scar forms a fixed obstacle that, in combination with the often intrinsically diseased atrial myocardium (providing functional obstacles) and normal structural obstacles in the vicinity of atrial incisions, can provide the substrate for macroreentry. Following mitral

valve surgery, low-voltage areas are often detected anterior to the right pulmonary veins (RPsVs), corresponding to LA incisions.⁹

Left Atrial Macroreentry Postablation of Atrial Fibrillation

LA MRAT is a frequent complication of surgical and catheter-based therapies of AF. The incidence and nature of ATs developing post AF ablation are, in large part, determined by the type of ablation performed and by the presence of abnormal LA substrate (see Chapter 15). The incidence seems to be lower following segmental ostial pulmonary vein (PV) isolation than circumferential PV isolation and higher following circumferential or linear LA ablation (more than 30%). The incidence of MRAT is much higher (more than 50%) for approaches of catheter ablation incorporating extensive lesions in the LA to terminate persistent AF. Linear ablation lesions, together with anatomical structures and intrinsically abnormal adjacent atrial myocardium, provide an ideal substrate for reentry. Gaps in the ablation lines further increase the chance for reentry by creating a region of slow conduction (see Fig. 13.1).

The most common form of macroreentry occurring after AF ablation is perimitral MRAT (accounting for approximately 40% of all MRATs). Macroreentrant circuits traversing the LA roof account for approximately 20% (see Fig. 15.60). Less common sites of macroreentry involve the right or left PVs, LA septum, and the base of the LA appendage (Fig. 13.3). Not infrequently, multiple macroreentrant circuits and multiple-loop reentrant circuits are encountered. In addition, localized reentrant circuits are not uncommon, and they usually arise from the vicinity of the isolated PVs or linear lesions.

LA MRATs comprise the majority of arrhythmias developing following surgical ablation of AF. Perimitral macroreentry is the most common, but macroreentry circuits incorporating the LA roof, septum,

and posterior wall, and circuits around the PVs have also been observed. Localized reentrant ATs comprise a sizable minority of the cases.¹⁰

Perimitral Left Atrial Macroreentry

This circuit involves reentry around the mitral annulus in a counter-clockwise or clockwise fashion (Fig. 13.4). The mitral annulus forms the anterior boundary of the reentry circuit, whereas the posterior boundary is formed by a low-voltage zone or scar in the posterior wall of the LA.

Perimitral MRAT is more common in patients with structural heart disease; however, it has been described in patients without obvious structural heart disease. In the latter group, voltage mapping often shows scar or low-voltage areas on the posterior wall of the LA forming the posterior boundary of the reentry circuit. As noted, perimitral macroreentry is the most common MRAT in patients with prior LA ablation procedures for AF, particularly when incomplete linear ablation across the lateral mitral isthmus is performed.¹¹

Circuits Involving the Pulmonary Veins

Various reentrant circuits involve the PVs, especially in patients with AF or mitral valve disease and those with prior catheter ablation of AF (particularly with linear LA ablation lesions), including circuits around one or more PVs (see Fig. 13.3) and posterior scar or low-voltage areas. PV-LA conduction recovery is frequently a critical element in these arrhythmias.

Left Septal Circuits

Left septal circuits occur primarily in patients with previous heart surgery, particularly after mitral valve surgery requiring septal incision, and

Fig. 13.3 Macroreentrant Atrial Tachycardia (MRAT) Around the Right Superior Pulmonary Vein (PV). Three-dimensional electroanatomic (Rhythmia) activation map of the left atrium (LA) during MRAT (tachycardia cycle length, 274 milliseconds) in a patient with prior wide-area circumferential PV ablation. Right lateral (A) and right posterior oblique (B) views are shown. The path of the reentry circuit, as delineated by the black arrow, uses gaps in the circumferential ablation line around the right-sided PVs. LAA, Left atrial appendage; LIPV, left inferior PV; LSPV, left superior PV; RIPV, right inferior PV; RSPV, right superior PV.

Fig. 13.4 Perimitral Macroreentrant Atrial Tachycardia. Surface electrocardiograms and intracardiac recordings during clockwise (*lower panel*) and counterclockwise (*upper panel*) perimitral macroreentrant atrial tachycardia. Catheter position and wavefront activation during the tachycardia are illustrated in a left anterior oblique fluoroscopic view (*right side*). The ablation catheter (*ABL*) is positioned at the mitral isthmus, and the Halo catheter is positioned around the tricuspid annulus (*TA*), with the distal end at the lateral end of the cavotricuspid isthmus. *AFL*, Atrial flutter; *CS*, coronary sinus; *CS_{dist}*, distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *TA_{dist}*, distal tricuspid annulus; *TA_{prox}*, proximal tricuspid annulus.

those with prior AF ablation. Rarely, MRATs involving the LA septum have been reported in the absence of prior cardiac surgery. These circuits involve the septum primum, which acts as a central obstacle for the reentrant circuit. The right PV ostia serve as its posterior boundary, whereas the mitral annulus serves as the anterior boundary. Atrial dilation and concomitant antiarrhythmic drug therapy also appear to play a role by the prolongation of left intraatrial conduction, which then allows stable macroreentry circuits to persist. In patients with a history of surgery for atrial septal defects, scars or the patch on the septum can serve as the anatomical substrate of left septal circuits.⁹

Left Atrial Macroreentry in the Absence of Previous Surgery or Ablation

LA circuits can be found in patients without a history of atriotomy or prior ablation. Electroanatomic maps in these patients often show electrically silent (low-voltage or scar) areas in the LA, which act as a central obstacle or barrier in the circuit. The pathogenesis of these areas with no electrical signals is not well established. Potential causes include

volume and pressure overload (mitral valve disease, hypertension, heart failure), ischemia (atrial branch occlusion), postinflammation scarring (after myocarditis), atrial amyloidosis, atrial dysplasia, and tachycardia-related structural remodeling. These conditions are frequently associated with diffuse or patchy areas of scarring, which are typically located at the posterior wall (45%), roof (28%), or anteroseptal region (27%) of the LA. The macroreentrant circuits in these patients show considerable anatomical variability and frequently involve multiple simultaneous loops (dual- or triple-loop reentry, or figure-eight reentry).^{12,13}

EPIDEMIOLOGY

MRAT comprises a heterogeneous group of ATs related to different anatomical and electrophysiological (EP) substrates. These arrhythmias are frequently associated with structural heart disease, congenital cardiac defects, previous cardiac surgical procedures, or surgical or catheter ablation procedures for AF. However, MRAT occasionally occurs in a patient with no apparent structural heart disease. Often, these

arrhythmias coexist with AF. Not infrequently, these patients experience sinus node dysfunction (SND), which can be symptomatic or hinder pharmacological therapy of the tachycardia.

Although its exact prevalence among cardiac arrhythmias is difficult to establish clinically, MRAT is not a rare arrhythmia. In fact, the incidence of MRAT has been increasing, likely due to aging of the general population, which implies progressive alteration of the atrial electrical properties with development of an arrhythmogenic substrate, and also due to the rapid growth of surgical and catheter-based ablation procedures for treatment of AF.

CLINICAL PRESENTATION

MRATs are typically persistent. As with AF and typical AFL, patients may present with symptoms related to rapid ventricular response, loss of atrioventricular (AV) synchrony, tachycardia-induced cardiomyopathy, or deterioration of preexisting cardiac disease. In addition, typical AFL and MRAT can contribute to systemic thromboembolic complications and stroke.

The clinical presentation of MRAT can vary widely, from completely asymptomatic to severe hemodynamic compromise. Most patients present with a spectrum of symptoms including palpitations, lightheadedness, fatigue, reduced activity tolerance, and dyspnea. Severe heart failure or acute coronary syndrome can occur in susceptible patients.

INITIAL EVALUATION

Outside typical AFL, the clinician is faced with a wide spectrum of ATs for which therapy and prognosis cannot be defined with routine non-invasive testing, and definitive diagnosis typically requires intracardiac mapping. ECG alone is frequently inadequate to distinguish MRAT from focal AT. Detailed evaluation of cardiac function and anatomy is typically required, especially in patients with congenital heart disease and those with previous cardiac procedures (surgical or catheter based). In addition, detailed knowledge of the congenital anomaly and previous surgical or ablative procedures is very important, such as location of surgical incisions and the presence and location of prosthetic patch material.

PRINCIPLES OF MANAGEMENT

Medical management of MRAT is practically similar to that described for typical AFL (see Chapter 12), including pharmacological rate- and rhythm-control strategies, as well as long-term anticoagulation for stroke. The choice of rate- versus rhythm-control strategies typically considers several factors, including severity of symptoms, response to rate-controlling medications, cardiac function, and associated noncardiac diseases.

With recent advances in the technology to visualize and modify the arrhythmia substrate, ablation of MRAT has become increasingly successful, but can be substantially more difficult than ablation of typical AFL. MRAT can have complex circuits that demand a thorough knowledge of atrial anatomy and a great level of experience to correlate activation patterns with anatomical landmarks. When this type of AT is suspected, such as in patients with congenital heart disease who have had surgery, referral to an experienced center should be considered.

Currently, catheter ablation is recommended in patients with recurrent symptomatic MRAT that is refractory to antiarrhythmic drug therapy, and may also be reasonable as a primary therapy, after carefully weighing potential risks and benefits of treatment options in the individual patient.¹⁴

ELECTROCARDIOGRAPHIC FEATURES

P wave morphology on the surface ECG is usually of limited value for precise anatomical localization of macroreentrant circuits. Analysis of the P wave can be impeded by partial or complete concealment of the P wave within the QRS complexes or T waves when the AT is associated with 1:1 or 2:1 AV conduction. In addition, P wave morphology of a spectrum of RA and LA MRATs is highly variable. The presence of complex anatomy secondary to congenital abnormalities, prior atrial surgery, or a large low-voltage zone (secondary to underlying atrial substrate or extensive catheter or surgical atrial ablation) can modify atrial wavefront propagation in a nonuniform manner, resulting in deviated atrial activation vectors or low-amplitude P waves. Furthermore, P waves produced by different underlying substrates may appear similar if the direction of activation of the atrial septum and LA is similar.

The surface ECG morphology is most characteristic (and hence predictive) for establishing a diagnosis of counterclockwise typical AFL. Nevertheless, atypical ECG patterns have been described for typical AFL after AF ablation. Although clockwise typical AFL also has a characteristic appearance, this is more variable, and it can be mimicked by various other MRATs ("pseudo-typical" morphology). On the other hand, AFL may show distinct isoelectric intervals between P waves, especially in the presence of extensive atrial scarring or a localized macroreentrant circuit, similar to focal AT.⁸

Despite significant limitations, certain ECG features have been demonstrated to help distinguish between the various types of MRAT. To distinguish LA from RA origin of the MRAT, lead V₁ is the most useful. In the absence of previous cardiac surgery or catheter ablation (particularly linear ablation lesions in the LA), P waves that are completely negative in lead V₁ are more frequently associated with RA free-wall circuits. Conversely, in the absence of counterclockwise typical AFL, broad-based upright P waves in lead V₁, especially when accompanied by upright waves in inferior leads or with low-amplitude or isoelectric waves in the other leads, are more frequently associated with LA circuits. LA circuits frequently generate low-amplitude P waves, with some of them having visible waves only in lead V₁.^{2,8} A decreased amplitude of the P waves in the inferior leads is suggestive of LA origin of MRAT. For ATs post AF ablation, negative P waves in any of the precordial leads favors RA MRAT over LA MRAT with a sensitivity and specificity of 83% and 100%, respectively, and an accuracy of 98%. Among LA MRATs, prominent positive flutter waves in lead V₁ favor LA roof or mitral isthmus-dependent MRATs over other LA MRATs, with a sensitivity and specificity of 80% and 83%, respectively, and an accuracy of 81%.¹⁵

In general, a positive P wave in the inferior leads can be observed in clockwise typical AFL, upper loop reentry, and LA macroreentry. P wave polarity in lead I can help distinguish upper loop reentry from clockwise typical AFL. A negative or flat flutter wave polarity in lead I favors upper loop reentry, whereas positive polarity with amplitude of more than 0.07 mV indicates clockwise typical AFL.¹⁶

Right Atrial Macroreentry

Incisional Right Atrial Macroreentry

The surface ECG morphology of free-wall MRAT in a patient with a previous atriotomy is highly variable, depending on factors including the location of the scars and low-voltage areas, the direction of rotation, the presence of coexisting conduction block in the atrium, and the presence of a simultaneous typical AFL. The morphology of the atrial complex on the surface ECG can range from that similar to typical AFL to one characteristic of focal AT (see Fig. 14.3). Often, inverted P waves can be observed in lead V₁. Depending on the predominant direction

of septal activation, RA free-wall MRAT can mimic clockwise or counterclockwise typical AFL.^{8,17}

Upper Loop Reentry

The surface ECG of upper loop reentry closely mimics that of clockwise typical AFL (negative P waves in lead V₁ and positive P waves in the inferior leads) because, in most cases, both arrhythmias share a similar activation sequence of the LA, the septum, and caudocranial activation of the lateral RA. However, negative or isoelectric or flat P waves in lead I favor upper loop reentry over clockwise typical AFL. Conversely, positive P waves in lead I with an amplitude of more than 0.07 mV favor clockwise typical AFL. In addition, the CL of upper loop reentry is usually shorter in comparison with typical AFL.⁸

Lower Loop Reentry

The surface morphology of lower loop reentry is highly variable and can be similar to that of counterclockwise or clockwise typical AFL, but lower loop reentry associated with somewhat higher crista terminalis breaks can produce unusual ECG patterns. Sometimes, the changes are manifested by decreased amplitude of the late positive waves in the inferior leads, probably as a result of wavefront collision over the lateral RA wall.⁸

Intra-Isthmus Reentry

The surface ECG in intra-isthmus reentry commonly exhibits a pattern similar to counterclockwise typical AFL. The same ECG pattern can exist whether the intracardiac atrial activation sequence around the tricuspid annulus exhibits a counterclockwise, clockwise, or fusion pattern. The proximity of the exit site of the reentrant circuit to the CS os promotes more rapid CS and septal activation of the LA, which largely determine inscription of the P wave, regardless of the peritricuspid activation pattern.⁴

Left Atrial Macroreentry

The surface ECG morphology of LA MRAT caused by the different reentrant circuits is variable, and ECG findings are often similar for different underlying substrates, thus making the localization within the LA based on the ECG difficult. LA MRATs are usually associated with prominent positive P waves in lead V₁ and upright (but frequently of low amplitude) deflections in leads II, III, and aVF. However, LA MRAT can result in ECG patterns of focal AT (discrete P waves and isoelectric baseline) because of a high prevalence of generalized atrial disease and slower conduction. Infrequently, LA MRAT can mimic typical AFL on the surface ECG.⁸

Perimitral Left Atrial Macroreentry

Most of these tachycardias show prominent forces in leads V₁ and V₂, with diminished amplitude in the inferior leads (see Fig. 13.4). It has been suggested that a posterior LA scar allows for domination by anterior LA forces. This constellation of findings can mimic counterclockwise or clockwise typical AFL, but the decreased amplitude of frontal plane forces suggests an LA circuit. In patients with prior PV isolation procedures, the surface ECG morphology of counterclockwise perimitral MRAT can be different from that in patients without prior ablation, possibly related to varying degrees of prior LA ablation or scar. In these patients, counterclockwise perimitral MRAT demonstrates positive P waves in the inferior and precordial leads and a significant negative component in leads I and aVL. Furthermore, counterclockwise perimitral MRAT in these patients can have a morphology similar to that of left PV ATs. However, counterclockwise perimitral MRAT is suggested in the presence of a more negative component in lead I, an initial negative component in lead V₂, and a lack of any isoelectric interval between P

waves. Clockwise perimitral MRAT has a limb lead morphology that is the converse of counterclockwise perimitral MRAT and an initial negative component in the lateral precordial leads. Positive P wave in leads I and aVL differentiates clockwise perimitral MRAT from counterclockwise CTI-dependent AFL and left PV AT.¹⁸

Pulmonary Vein Circuits

Because these circuits are related to low-voltage or scar areas, the surface ECG usually shows low-amplitude or flat P waves. These tachycardias have the most variable surface ECG patterns.

Left Septal Circuits

Because the reentry circuit is on the septum, the surface ECG shows prominent, usually positive, P waves only in lead V₁ or V₂ and almost flat waves in most other leads (eFig. 13.1). This pattern can be caused by a septal circuit with anteroposterior forces projecting in lead V₁ and the cancellation of caudocranial forces. This pattern was 100% sensitive for an LA septal circuit, but the specificity of this pattern for any type of LA MRAT was only 64%.

ELECTROPHYSIOLOGICAL TESTING

A decapolar catheter (positioned into the CS with the proximal electrodes bracketing the CS os) and a multipolar (20- or 24-pole) Halo catheter (positioned at the tricuspid annulus) are commonly used to map MRAT. The distal tip of the Halo catheter is positioned at 6 to 7 o'clock in the left anterior oblique (LAO) view, so that the distal electrodes will record the middle and lateral aspects of the CTI, the middle electrodes will record the anterolateral RA, and the proximal electrodes may record the RA septum (depending on the catheter used). Instead of the Halo and CS catheters described, some laboratories use a single duodecapolar catheter around the tricuspid annulus while extending the catheter tip inside the CS. Such a catheter would straddle the CTI and provide recording and pacing from the medial and lateral aspects of the CTI.

Induction of Tachycardia

Programmed electrical stimulation protocols usually include atrial burst pacing from the high RA and CS—down to a pacing cycle length (PCL) at which 2:1 atrial capture occurs—and single and double atrial extra-stimuli (AES) at multiple PCLs (600 to 300 milliseconds) from the high RA and CS (down to the atrial refractoriness). Isoproterenol infusion (0.5 to 4 µg/min) is administered as needed to facilitate tachycardia induction. The goals of EP testing in patients with MRAT are listed in Box 13.1.

Tachycardia Features

MRAT is characterized by a constant TCL, a constant P wave morphology, and a constant atrial activation sequence. The atrial activation sequence depends on the origin and type of the macroreentrant circuit.

Although the atrial CL during MRAT typically remains constant, considerable variations in the CL can be observed in the atrium contralateral to atrium of origin of the tachycardia (Fig. 13.5). In contrast, focal ATs frequently exhibit alterations in the CL with speeding (warm-up) and slowing (cool-down) at the onset and termination of tachycardia. Variation in the TCL of greater than 15% has been suggested as a reliable marker of a focal AT. However, a regular AT can be focal or macroreentrant. In addition, focal ATs often manifest as bursts of tachycardia with spontaneous onset and termination, although they can be incessant, and they may accelerate in response to sympathetic stimulus. Several criteria can help distinguish focal AT from MRAT (see Table 11.5).⁸

eFig. 13.1 Surface Electrocardiogram of Left Septal Macroreentrant Atrial Tachycardia. The tachycardia developed in a patient with tachycardia-bradycardia syndrome and a permanent pacemaker. The P waves are masked by the QRS and T waves during 2:1 atrioventricular conduction. Administration of adenosine results in atrioventricular block and reveals P wave morphology. Note the prominent positive P waves only in lead V₁ and almost flat waves in most of the other leads.

Atrial activation during MRATs spans the whole TCL. In contrast, intracardiac mapping in the setting of focal ATs shows significant portions of the TCL without recorded atrial activity, and atrial activation time is markedly less than the TCL, even when recording from the entire cardiac chamber of tachycardia origin (see Fig. 11.5). However, in the presence of complex intramyocardial conduction disturbances, activation during focal tachycardias can extend over a large proportion of the TCL, and conduction spread can follow circular patterns suggestive of macroreentrant activation. On the other hand, long isoelectric

intervals can occur between P waves during MRATs; especially when mapping is limited to only the atrium contralateral to the origin of the macroreentrant circuit or to only parts of the ipsilateral atrium, a focal activation can be observed, incorrectly suggesting a focal mechanism. This is particularly observed for LA MRATs in the presence of large areas of electrical silence. Nonetheless, a *thorough* intracardiac activation mapping would reveal atrial activation spanning the TCL.

Occasionally, P wave morphology on the surface ECG resembles AT, but intracardiac recordings show that parts of the atria (commonly the LA) have disorganized atrial activity (Fig. 13.6). Such rhythms behave more like AF than AT, but they may be converted to true typical AFL with antiarrhythmic drugs.

MRAT is usually associated with 2:1 AV conduction, although variable AV conduction and larger multiples are not uncommon. Variable AV conduction is the result of multilevel block; for example, proximal 2:1 AV block and more distal 3:2 Wenckebach block result in 5:2 AV Wenckebach block. Macroreentrant circuits can have long CLs (i.e., 250 to 400 milliseconds) in the presence of extensive atrial disease and antiarrhythmic agents, in which case a relatively rapid ventricular response (with 1:1 AV conduction) can occur.

Diagnostic Maneuvers During Tachycardia

Atrial Extrastimulation During Tachycardia

A focal mechanism is characterized by dissociation of almost the entire atria from the tachycardia with AES. In contrast, the MRAT circuit usually incorporates large portions of the RA or LA, as demonstrated by resetting. In response to AES, MRATs typically demonstrate an increasing or mixed (flat, then increasing) resetting response. AES usually fails to terminate the AT.

Importantly, AES at short coupling intervals can result in transformation of the tachycardia to a different AT or to AF. To minimize the risk of transformation or interruption of the tachycardia, which would hinder tachycardia mapping, atrial stimulation maneuvers during the tachycardia should be used sparingly and only when needed to confirm the diagnosis, or more precisely, to localize the critical portion of the AT circuit as guided by the initial activation mapping.

BOX 13.1 Goals of Programmed Stimulation During Macroreentrant Atrial Tachycardia

1. To confirm that the tachycardia is an AT
2. To confirm that the AT is a macroreentrant circuit
 - Resetting response consistent with reentry
 - Entrainment mapping consistent with reentry
 - Atrial activation spanning the TCL
3. To exclude CTI-dependent atrial flutter
 - Entrainment mapping at the CTI
4. To localize the circuit to the RA versus LA
 - P wave morphology on the surface ECG
 - Atrial activation sequence in the CS and Halo catheters
 - Isolated variation of the RA CL
 - RA activation time <50% of the TCL
 - Entrainment pacing from different RA sites
5. To define the tachycardia circuit
 - Electroanatomic mapping
 - Entrainment mapping
6. To define the critical isthmus in the tachycardia circuit
 - Entrainment mapping

Fig. 13.6 Localized Atrial Macroreentry. Surface 12-lead electrocardiogram (ECG) and intracardiac recordings during left atrial tachycardia (AT) that use a small macroreentrant circuit near the ostium of the right superior pulmonary vein (PV) in a patient with prior extensive wide-area circumferential PV ablation and linear ablation for atrial fibrillation (AF). On the left, P waves are separated by isoelectric intervals, mimicking focal AT, as a result of extensive scarring in the left atrium. In the middle of the recording, the AT converts spontaneously to AF. Note that the intracardiac recordings demonstrate grossly irregular atrial activity during AF as compared with AT; however, on the surface ECG, atrial activity remained relatively organized, and conversion from AT into AF was manifest on the surface ECG by a change in rate and minor changes in morphology of atrial complexes. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus.

Atrial Pacing During Tachycardia

Burst pacing from the CS or along the Halo catheter is started at a CL 10 to 20 milliseconds shorter than the atrial CL, and then the PCL is progressively shortened by 10 to 20 milliseconds. Consistent capture by atrial stimuli and acceleration of all recorded atrial electrograms to the paced rate should be verified before analyzing the tachycardia response to overdrive pacing. The response of AT to overdrive pacing is evaluated for entrainment, overdrive suppression, transformation into distinct AT morphologies or AF, and ability and pattern of termination.

Entrainment. Overdrive atrial pacing at long CLs (i.e., 10 to 30 milliseconds shorter than the TCL) can usually entrain MRAT. The slower the pacing rate and the farther the pacing site from the reentrant circuit, the longer the pacing drive required to penetrate and entrain the tachycardia. Achievement of entrainment of the AT establishes a reentrant mechanism of the tachycardia and excludes triggered activity and abnormal automaticity as potential mechanisms (Fig. 13.7). Entrainment can also be used to estimate qualitatively how far the reentrant circuit is from the pacing site (see later).¹⁹

Entrainment criteria. During constant-rate pacing, entrainment of a reentrant tachycardia results in the activation of all myocardial tissue responsible for maintaining the tachycardia at the PCL, with the resumption of the same tachycardia morphology following cessation

of pacing, with the first postpacing ECG tachycardia complex displaying no fusion but occurring at a return cycle equal to the PCL. Unfortunately, it is almost impossible to document the acceleration of all tissue responsible for maintaining the reentrant circuit to the PCL. Also, it should be recognized that the mere acceleration of the tachycardia to the pacing rate and the subsequent resumption of the original tachycardia after cessation of pacing do not establish the presence of entrainment. Therefore several surface ECG and intracardiac electrogram criteria have been proposed for establishing the presence of entrainment (see Box 5.2). Demonstration of one or more of the four criteria proves the presence of entrainment and supports a reentrant mechanism, but their absence does not exclude entrainment or reentry. Pacing at different endocardial sites and at multiple PCLs and recording activation sequences from multiple intracardiac locations are often required to demonstrate one or more of the entrainment criteria and, hence, establish the diagnosis of macroreentrant tachycardia.^{20,21}

Entrainment with fusion. During entrainment of MRAT, fusion of the stimulated impulse can be observed on the surface ECG, but it is easier to recognize on intracardiac recordings from the Halo and CS catheters. The stimulated impulse has a hybrid morphology between the fully paced atrial impulse and the tachycardia impulse. The ability to demonstrate surface ECG fusion requires a significant mass of atrial myocardium to be depolarized by the paced stimulus and by the

Fig. 13.7 Entrainment of Counterclockwise Perimitral Macroreentrant Atrial Tachycardia. (A) Entrainment from the distal coronary sinus (CS) results in intracardiac atrial fusion (as demonstrated in the CS activation sequence) and a short postpacing interval (PPI) compared to the tachycardia cycle length (TCL) ($PPI - TCL = 14$ milliseconds) because the distal CS is close to the reentrant circuit. (B) Entrainment from the ablation catheter (ABL) positioned at the cavotricuspid isthmus (CTI) results in manifest atrial fusion with a long PPI ($PPI - TCL = 150$ milliseconds), suggesting that the CTI is not part of the reentrant circuit. *Continued*

C

Fig. 13.7, cont'd (C) Entrainment from the ablation catheter positioned at the mitral isthmus, concealed atrial fusion, and a short PPI (PPI – TCL = 18 milliseconds), suggesting that the mitral isthmus is the critical isthmus of the reentrant circuit. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; TA_{dist}, distal tricuspid annulus; TA_{prox}, proximal tricuspid annulus.

tachycardia. The closer the stimulation site is to the exit of a reentrant circuit, the less likely entrainment will manifest ECG fusion.

It is important to understand that overdrive pacing of a tachycardia of any mechanism can result in a certain degree of fusion, especially when the PCL is only slightly shorter than the TCL. Such fusion, however, is unstable in focal tachycardias during the same pacing drive at a constant PCL because pacing stimuli fall on a progressively earlier portion of the tachycardia cycle, thus producing progressively less fusion and more fully paced morphology. Such phenomena (referred to as “variable fusion”) should be distinguished from “constant fusion” and “progressive fusion” characteristic of entrainment, and sometimes this requires pacing for long intervals to demonstrate variable degrees of fusion. Focal ATs (automatic, triggered activity, or microreentrant) cannot manifest stable fusion during overdrive pacing (i.e., overdrive pacing during focal AT results in a fully paced P morphology and intracardiac activation sequence). Moreover, overdrive pacing frequently results in suppression (automatic) or acceleration (triggered activity) of focal ATs, rather than resumption of the original tachycardia with an unchanged TCL.^{20,21}

Entrainment with manifest fusion. Entrainment of MRATs commonly produces manifest fusion that is stable (fixed) during pacing at a given PCL. Repeated entrainment at PCLs progressively shorter than the TCL results in different degrees of fusion between pacing episodes (while showing fixed fusion within any given episode of pacing), with the resultant P wave configuration looking more like a fully paced configuration as the paced rate increases.

Demonstration of the presence of manifest fusion during entrainment requires knowledge of the tachycardia surface P wave morphology and of pure pacing (at the same site and rate) in the absence of tachycardia. However, in the setting of MRAT, P wave morphology during tachycardia or pure pacing may not be easily visualized in the presence of overlapping QRS complexes and ST-T waves; hence, the intracardiac atrial activation sequence can be utilized as a surrogate to ECG morphology to demonstrate fusion and is preferable due to the ability to have many discrete recordings for comparison of paced versus tachycardia sequences. Manifest fusion is said to be present when the ECG morphology (or intracardiac activation sequence) is a hybrid of the complex morphology of the tachycardia and that observed during pure pacing.

However, fusion can sometimes be difficult to recognize on the surface ECG because the morphology of the purely paced ECG complex may not be readily available. In this setting, the presence of manifest fusion can be inferred by one of the following observations:

1. The surface P wave during entrainment is different from pure tachycardia morphology and the onset of the P wave precedes the pacing stimulus artifact of each paced beat by a fixed interval (see Fig. 13.7; see Fig. 12.12). This observation provides evidence that the tachycardia wavefront has exited from the circuit, and that the initial portion of the P wave (inscribed before the pacing stimulus artifact) is activated orthodromically by the tachycardia wavefront while the latter portion is activated by the paced wavefront.
2. The surface P wave morphology (or intracardiac activation sequence) is different from the pure tachycardia morphology but is inconsistent with the expected morphology during pure pacing at a particular site (for example, AT entrainment from the distal CS producing a proximal-to-distal CS activation sequence).
3. The demonstration of shortening of conduction time (and change in electrogram morphology) at an intracardiac electrode recording site in response to increasing pacing rates during entrainment. Because conduction velocity with an increasing rate is expected to stay the same or decrease, but not increase, a decrease in conduction time (same paced site, same recorded site) in relation to a faster pacing rate demonstrates that there are two routes of activation and that the faster one can only conduct to the recording site at faster pacing

rates. This represents the “fourth” entrainment criterion and is the intracardiac equivalent of the second entrainment criterion (progressive fusion). The amount of tissue antidromically captured is critically dependent on the pacing rate. If the recording site is located in an area activated orthodromically at a slower rate and antidromically at a faster rate, the conduction time will dramatically shorten at the faster pacing rate.²²

4. The demonstration of pacing from electrodes on a multipolar catheter that have late activation times, results in acceleration of electrograms recorded from other electrodes on the same catheter that had earlier activation times during tachycardia (Fig. 13.8). This downstream pacing affecting upstream recordings has been shown to correlate with macroreentry with high specificity.

Entrainment with inapparent fusion. Entrainment with inapparent fusion (also referred to as “local” or “intracardiac” fusion) is said to be present when a fully paced P morphology (with no ECG fusion) results, even when the tachycardia impulse exits the reentrant circuit (orthodromic activation of the presystolic electrogram is present). In this setting, fusion is limited to a small area and does not produce surface ECG fusion, and only intracardiac (local) fusion can be recognized (and even then, only with recording electrodes in the correct location).

Entrainment with concealed fusion. Entrainment with concealed fusion (sometimes also referred to as “concealed entrainment” or “exact entrainment”) is defined as entrainment with orthodromic

Fig. 13.8 Entrainment of Scar-Related Macroreentrant Right Atrial Tachycardia. Overdrive pacing is performed from the lateral right atrium (Halo 7–8), a site that is “downstream” from other electrodes with earlier activation during tachycardia, but nonetheless controls electrograms that are “upstream” from it on the next cycle. Electrograms shaded in blue are activated at a paced cycle length, indicating they are controlled by the last pacing stimulus, whereas electrograms shaded in red are activated at the tachycardia cycle length. This phenomenon is an indicator of macroreentry.

capture and a surface ECG complex identical to that of the tachycardia. Entrainment with concealed fusion suggests that the pacing site is within a protected isthmus, either inside or outside of, but attached to, the circuit's diastolic corridor.

Pacing in a protected isthmus, either inside or outside or attached to the reentrant circuit isthmus, forces the paced wavefront to travel in one (orthodromic) direction through the same reentrant pathway as the tachycardia wavefront. Propagation of the paced wavefront in the opposite (antidromic) direction is prevented by either a dead end (when one end of the protected isthmus is attached to the circuit and the other end is a dead end) or by colliding with the previous reentrant wavefront propagating orthodromically through the reentrant circuit (when both ends of the protected isthmus are attached to the circuit, whether the isthmus is critical to the circuit or just a bystander). In either situation, the paced wavefront is forced to use the same reentry circuit exit to activate the rest of the atrial myocardium and is prevented from activating the myocardium by propagating in any other direction. Hence, the entrained P wave morphology is identical to that of the tachycardia.^{19,20}

Termination. Rapid atrial burst pacing can usually terminate MRAT. However, termination is less likely when the pacing drive is short or the pacing site is distant from the reentrant circuit. It is important to avoid unintended termination of MRAT because it can be very difficult to reinitiate the clinically relevant AT, particularly in a patient with complex scar and multiple potential circuits.

Overdrive suppression. Overdrive suppression analogous to that seen with automatic AT is not expected in MRAT. As noted, the PPI remains relatively stable when entrainment of MRAT is performed at the same site, regardless of the length of the pacing drive. This is in contrast to overdrive suppression seen in automatic ATs, which would be associated with progressive delay of the first tachycardia beat return cycle with progressively longer pacing drives.

Transformation. Rapid atrial burst pacing can potentially convert MRAT to AF, to typical AFL, or to another type of MRAT. The risk of tachycardia transformation is significant, especially given the frequent prevalence of complex combinations of anatomic and functional obstacles that can support multiple reentrant circuits. Therefore pacing maneuvers during AT should be used sparingly, and only when necessary to confirm the role of critical areas of the circuit (during entrainment mapping, as discussed later). Detection of tachycardia transformation requires careful attention to the atrial activation sequence and the ECG pattern after cessation of pacing. Also, recording multiple simultaneous electrograms on multipolar catheters (e.g., Halo and CS catheters), as continuous endocardial references, facilitates detection of changes in atrial activation sequence.

MAPPING

Detailed knowledge of the congenital anomaly, surgical procedure, and previous ablation strategy, if present, is important in interpreting the results of mapping, in knowing how to access the RA, in assessing the feasibility of the transseptal puncture, and in determining whether fluoroscopy is helpful in localizing the catheters or whether intracardiac echocardiography or transesophageal echocardiography is needed.

The goals of mapping of macroreentrant circuits include localization of the tachycardia circuit (RA vs. LA), identification of circuit boundaries and possible lines of block in relation to atrial anatomy, and identification of the vulnerable segment (critical isthmus) of the reentry circuit in order to guide a specifically tailored ablation strategy. Mapping is best achieved by the combined use of multipolar catheters, a three-dimensional (3-D) electroanatomic mapping system, and entrainment mapping.

The use of a multipolar Halo catheter in the RA (in addition to the CS catheter) is helpful for mapping not only RA MRATs, but also LA MRATs. This catheter allows rapid visualization of an ascending or descending atrial activation sequence and can suggest the location of the reentry circuit (RA vs. LA). In addition, recording in the lateral RA can help identify a scar or line block (by exhibiting low amplitude or double potentials), a common substrate in MRATs. Simultaneous recording of RA activation and CS activation (using a decapolar catheter) can also help rapid identification of tachycardia transformation that may occur during mapping and ablation.

Electroanatomic Mapping

Because the reentrant circuit can involve any of multiple barriers that are frequently removed from fluoroscopic markers, conventional mapping and anatomically guided ablation, as performed for typical CTI-dependent AFL, are not feasible in the majority of MRAT cases. Therefore a 3-D electroanatomic mapping system (CARTO [Biosense Webster, Inc., Diamond Bar, CA] or EnSite NavX [St. Jude Medical, St. Paul, MN]) is typically utilized to help distinguish between a focal origin and macroreentrant tachycardia by providing a precise description of the macroreentrant circuit and sequence of atrial activation during the tachycardia and rapid visualization of the activation wavefront (eFig. 13.2). This can contribute to the understanding of the reentrant circuit in relation to native barriers and surgical scars, identification of all slow-conducting pathways and appropriate sites for entrainment mapping, planning of ablation lines, navigation of the ablation catheter, and verification of conduction block produced by radiofrequency (RF) ablation. Mapping systems also provide the capability to create and tag points of interest during the mapping process (e.g., double potentials and sites with good entrainment findings) and return to them with great precision, as well as denoting sites that should be avoided when ablating (e.g., His bundle [HB] region).

The main goal of activation mapping of MRAT is identification of the complete reentrant circuit and its mid-diastolic critical isthmus. Unlike mapping focal AT, whereby tracking the site with the earliest presystolic local activation timing is the goal of mapping, there is no early or late region for MRAT because the wavefront is continuously propagating around the circuit. Activation can be continuously mapped, and an "earlier" activation time can always be found for any particular point of the circuit. Endocardial recordings often show activation during the isoelectric intervals on the surface ECG. The concept of "early activation" is not applicable to any particular site in the reentrant circuit. Nevertheless, for illustrative purposes, a particular reference point may be designated as the origin of activation (time 0), but it should be understood that this is always arbitrary.

Mapping Technique

Initially, the reference electrogram is selected to compare the timing of sites sampled by the mapping catheter, the anatomical reference is positioned, and the window of interest is defined. The reference catheter is usually placed in the CS (because of its stability); it is important to select a recording with a prominent atrial electrogram and ensure that the ventricular electrogram is not the one detected by the system. The onset of the window of interest is usually set at the mid-diastole between two consecutive P waves with a window duration spanning 90% to 95% of the TCL.

Then, the mapping catheter is used to collect geometry information. Anatomical and EP landmarks (IVC, SVC, CS, HB, and tricuspid annulus for RA mapping, and mitral annulus and PVs for LA mapping) are marked. Identification of those anatomical fixed barriers is very important to help understand propagation of the reentrant activation wavefront in relation to these barriers, identify the tachycardia critical isthmus,

eFig. 13.2 Electroanatomic (CARTO) Mapping of the Macroreentrant Right Atrial (RA) Tachycardia. Mapping was performed during sustained tachycardia in a patient with previous right atriotomy for severe tricuspid valve disease. The right posterolateral view of the RA is presented. (A) Activation map. (B) Bipolar voltage map demonstrates a large area of low bipolar electrogram amplitude (<0.5 mV) in the lateral RA wall at the site of prior surgery. (C) Isochronal map. (D–H) Propagation map demonstrating revolution of the reentrant wave front in a clockwise fashion around the lateral RA low-voltage zone. Visualization of the reentry circuit is facilitated by correlating activation mapping findings with those of voltage mapping. CS, Coronary sinus; IVC, inferior vena cava; SVC, superior vena cava.

and plan an ablation strategy to abolish the tachycardia. Subsequently, the mapping catheter is used to create a virtual model of the endocardial surface of the atrium of interest. This can be performed during normal sinus rhythm (NSR) before induction of tachycardia, or during tachycardia and in conjunction with activation mapping.

Once chamber geometry has been delineated, activation mapping is performed to define the atrial activation sequence. Activation mapping is performed during stable (spontaneous or induced) tachycardia. Importantly, variation of the TCL by more than 10% can potentially prevent complete understanding of the circuit and limit the confidence in the electroanatomic map.

For activation mapping, each point is tagged on the 3-D map as follows: The local activation time at each site is determined from the intracardiac bipolar electrogram and is measured in relation to the fixed intracardiac electrogram obtained from the CS (electrical reference) catheter. Using the onset of the local bipolar electrogram is preferable because it is easier to determine reproducibly when measuring heavily fractionated, low-amplitude atrial electrograms. Points are added to the map only if stability criteria in space and local activation time are met. The end-diastolic location stability criterion is a variation of less than 2 mm, and the local activation time stability criterion is less than 2 milliseconds.

Reasonable numbers of points homogeneously distributed in the RA or LA, or both, must be recorded. Current electroanatomic mapping systems enable rapid activation mapping by the simultaneous acquisition of activation information from multiple electrodes (e.g., circular mapping catheter or PentaRay catheter [Biosense Webster, Diamond Bar, CA, United States]).²³

During the process of activation mapping, acquired conduction barriers encountered by the roving catheter (including surgical incisions, patches, and scars) need to be identified and tagged on the mapping system, otherwise, the mapping system will fill those areas through interpolation of simple estimates of activation timing, resulting in misleading maps. Lines of block (manifest as double or split atrial potentials with two or more discrete electrical activation events per beat separated by a clearly discernible isoelectric period) are tagged for easy identification because they can serve as boundaries for a subsequent ablation strategy design. Silent areas are defined as having an atrial potential amplitude lower than 0.05 mV and the absence of atrial capture at 20 mA (provided that catheter contact is verified). Such areas and surgically related scars, such as atriotomy scars in the lateral RA or atrial septal defect closure patches, are tagged as “scar” (see Figs. 14.1 and 14.2). At sites with double potential, entrainment of the tachycardia can help evaluate which potentials are captured by the pacing stimulus. Local activation times are then reviewed, and the apparent far-field signal is excluded from the activation maps. The activation map can also be used to catalog sites at which pacing maneuvers are performed during assessment of the tachycardia.

Localization of the Reentrant Circuit Chamber (Right Versus Left Atrium)

Analysis of RA and LA activation sequences as recorded by the peritricuspid Halo catheter and CS catheter can sometimes help predict the location of the reentry circuit. CS activation usually propagates in a proximal-to-distal direction in the setting of RA MRATs and in a distal-to-proximal direction in the setting of LA MRATs. However, this is not always true; MRATs localized to the superior RA can result in distal-to-proximal CS activation, and some LA MRATs (e.g., counterclockwise perimitral MRAT) can activate the CS in a proximal-to-distal direction (see Fig. 13.4). *Chevron* and *reverse chevron* activation patterns in the CS suggest roof-dependent LA MRAT, whereby activation propagates down the LA posterior wall to activate the midposterior portion of the

mitral annulus before propagating medially and laterally (*chevron* pattern), or the tachycardia wavefront travels down the medial and lateral walls with later activation of the midposterior mitral annulus (*reverse chevron* pattern; Fig. 13.9).²⁴

In the absence of prior ablation of the CTI, an RA activation occurring sequentially in a proximal-to-distal direction along the Halo electrodes is suggestive of counterclockwise typical AFL. This sequence is reversed during clockwise AFL (see Fig. 12.1). In both types of typical AFL (counterclockwise and clockwise), activation of the CS propagates in a proximal-to-distal direction. A *chevron* activation pattern in the Halo catheter (with earliest activation at the atrial septum near the Bachmann bundle or CS os, and latest activation in the lateral RA free wall) suggests an LA origin.

If an LA origin of the tachycardia remains uncertain, limited entrainment mapping at selected sites may be considered (see below). Otherwise, activation mapping is started in the RA. Activation timing is sampled at selected sites in the RA to quickly define the chamber of origin of the AT (RA vs. LA). During LA MRATs, when mapping is limited to the RA, long segments of the TCL may not be covered by recorded electrograms. When activation timing from 10 roughly evenly distributed sites in the RA (including 3 or 4 points at the tricuspid annulus) spans less than 50% of the TCL (in the absence of extensive RA scarring or prior CTI ablation), an LA origin of the tachycardia is likely. One exception is the presence of a small reentrant RA circuit. Also, during LA macroreentry, RA mapping typically shows nonreentrant activation patterns, clearly different from typical clockwise and counterclockwise AFL. Early RA septal activation relative to other parts of the RA can suggest a focal septal origin in some cases when LA recordings are not obtained (see Fig. 13.4). Local RA conduction disturbances, such as CTI block (from prior isthmus ablation) or transverse block at the crista terminalis, can result in activation of the anterior and septal RA in opposite directions, which mimics reentrant RA activation of typical AFL. In these cases, entrainment mapping clarifies the location of the reentrant circuit (and, perhaps as importantly, which areas are not involved in the arrhythmia).

Activation Map

In atrial macroreentry, the 3-D electroanatomic activation map typically demonstrates a continuous progression of colors around a central obstacle with close proximity of earliest and latest local activation and an activation time in a range similar to the TCL (Fig. 13.10). Conversely, the electroanatomic maps of focal ATs demonstrate radial spread of activation, from the earliest local activation site in all directions. In these cases, total atrial activation time is markedly shorter than the TCL.

It is important to recognize that if an insufficient number of points is obtained, it may be falsely concluded, through the interpolation of activation times, that the wavefront propagates from a focal source (Fig. 13.11).²⁵ This is frequently encountered when the MRAT originates from the chamber contralateral to the one being mapped. In the latter situation, the activation map will localize the site of the earliest local activation to the earliest breakthrough of interatrial conduction. Notably, this breakthrough location, although having the earliest recorded activation timing in that chamber relative to the intracardiac electrical reference, may not be presystolic (as compared to the onset of the P wave on the surface ECG) and, hence, cannot be the site of origin of a focal tachycardia. This provides a further clue to help interpret the activation map and should prompt more detailed mapping.

The initial step is activation mapping to determine whether activation of the entire TCL can be recorded within the LA. In particular, mapping should be carefully carried out around the mitral annulus because this maneuver is easy to perform and identifies a common form of LA MRAT, perimitral MRAT. If comprehensive activation

Fig. 13.9 Atrial Activation Patterns in the Coronary Sinus During Roof-Dependent Left Atrial Macroreentry. Two patients with roof-dependent macroreentrant atrial tachycardias showing characteristic “chevron” activation patterns in coronary sinus (CS) recordings. In (A) a standard chevron is seen indicated by red arrows, whereas in (B) a so-called reverse chevron pattern is seen (blue arrows).

Fig. 13.10 Perimitral Macroreentrant Left Atrial Tachycardia. Three-dimensional electroanatomic (Rhythmia) activation map of the right atrium (A), left atrium (B), and both atria (C) in the left anterior oblique view constructed during counterclockwise perimitral macroreentrant atrial tachycardia. During tachycardia, the activation wavefront travels in a counterclockwise direction around the mitral annulus (MA), as indicated by a continuous progression of colors (from red to purple) with close proximity of earliest and latest local activation (red meeting purple). CS, Coronary sinus; LAA, LA appendage; MA, mitral annulus; SVC, superior vena cava; TA, tricuspid annulus.

Fig. 13.11 Electroanatomic Mapping During Macroreentrant Atrial Tachycardia. Posteroanterior view of left atrial (LA) electroanatomic (CARTO) activation map in a patient with atrial tachycardia following circumferential pulmonary vein (PV) isolation and LA roof linear ablation for treatment of atrial fibrillation. *Left*, The activation pattern suggests a focal process in the posterosuperior LA with centrifugal spread of activation from the central red area. *Right*, With additional detailed mapping on the LA roof (as reflected by higher density of small white dots; each dot represents a sampled endocardial site), a macroreentrant circuit around the left-sided PVs (and through a gap in the LA roof line) is evident. LIPV, Left inferior PV; LSPV, left superior PV; LAA, LA appendage; RIPV, right inferior PV; RSPV, right superior PV.

mapping in both atria does not cover most of the TCL, two possibilities must be considered: (1) focal AT, or (2) small, localized reentrant circuits, which require much more detailed activation mapping to be identified. Localized reentry should be considered if a local electrogram exhibits low-amplitude, long, fractionated potentials occupying more than 60% of the TCL, and the putative reentry is confined to a small region of one atrium (covering a surface diameter of <3 cm) with a centrifugal activation of the atria from this region. Entrainment with concealed fusion (see later) is only possible with pacing within the small reentry circuit.

Once a reasonable number of points homogeneously distributed in the chamber of interest are obtained, the complete reentrant circuit can be defined as the spatially shortest route of unidirectional activation encompassing the complete CL of the tachycardia in terms of activation timing and returning to the site of earliest activation. Activation wavefronts that do not fulfill these conditions are bystander wavefronts and are not critical to the tachycardia circuit. However, incomplete mapping can lead to confusion about the bystander status of a given activation wavefront or loop, and an incomplete loop can be mistaken for a complete one. High-density mapping or entrainment mapping can clarify this situation by documenting wavefront collision or a long PPI, respectively (see later).

For LA macroreentry, identification of the complete reentrant circuit can be challenging, especially in patients with repaired congenital heart disease, because of the complex suture lines or baffles. Entrainment then becomes an essential tool in these cases to confirm participation of specific areas in the circuit and to try to locate a suitable isthmus area for ablation (see later).

Recently, the Rhythmia mapping system (Boston Scientific Corp., Marlborough, MA, United States) has been used to perform ultrahigh-resolution contact activation mapping on atrial arrhythmias. With this system, a small semispherical basket catheter with eight splines and eight small, printed surface electrodes per spline records unipolar elec-

trograms as it is moved around the atrial chamber (see Fig. 13.1 and Fig. 13.3). Complex automated algorithms are used to analyze and validate very small signals by comparing them to signals from the same electrodes on consecutive complexes, as well as surrounding electrodes. With this, ultrahigh-density maps facilitate accurate delineation of propagation patterns, conduction isthmuses, and lines of preexisting block. Experience with this system in MRAT is limited but promising.^{26–28}

Identification of the Critical Isthmus

Zones of slow conduction, possibly critical to the maintenance of the MRAT circuit, are usually identified by low-amplitude fractionated atrial electrograms. High-density mapping is performed in and around those zones to define their relation to adjacent normal and abnormal conduction barriers. During macroreentry, an isthmus is defined as a corridor of conductive myocardial tissue bounded by nonconductive tissue (barriers) through which the depolarization wavefront must propagate to perpetuate the tachycardia. These barriers can be scar areas or naturally occurring anatomical or functional (present only during tachycardia, but not in sinus rhythm) obstacles. The earliest presystolic electrogram closest to mid-diastole is the most commonly used definition for the center of the isthmus of the reentrant circuit. Isthmuses within low-voltage or scar areas commonly exhibit fragmented or continuous potentials with low voltage and long activation duration.¹⁷

When double potentials separated by an isoelectric interval can be traced in a convergent configuration, with a progressively decreasing interpotential interval, and culminate in a fractionated continuous electrogram, this finding indicates one end of a line of block and activation through the resulting isthmus or around a pivot point at the end of the line of block. These findings should prompt further mapping maneuvers (entrainment mapping) to verify its role in the reentry circuit.

Importantly, electrograms recorded within the critical isthmus frequently exhibit very low amplitudes, likely related to very thin strands of myocardium responsible for diastolic conduction within a large scar

area. The interpretation of these local electrograms can be very difficult in the absence of the full electroanatomic activation maps supported with critical entrainment mapping to confirm participation of adjacent areas in the circuits.

Of note, the location where earliest activation and latest local activation meet (the “early meets late” or “head meets tail” points) can be anywhere along the reentry circuit, depending on the timing of the electrical reference (the zero point) arbitrarily chosen for activation mapping. That location has no inherent relation to the site of the critical isthmus of the reentry circuit. Nonetheless, when the onset of the window of interest is set at the mid-diastole between two consecutive P waves, the region where “early meets late” on the color-coded activation map can potentially correlate with the mid-diastolic isthmus of the reentrant circuit.

Voltage Map

Voltage mapping is performed to define areas of electrical scars, which can be involved in the reentrant circuit or can potentially serve as boundaries for subsequent ablation design strategies (see eFig. 13.2). Atrial bipolar potentials with an amplitude of 0.5 mV or less are typically considered abnormal and termed low-voltage areas. Silent areas (scar) are defined as having an atrial bipolar potential amplitude of less than 0.05 mV and the absence of atrial capture at 20 mA. Superimposition of a bipolar voltage map on the activation map can also help focus auditing of the activation map to areas where low amplitude potentials are recorded. Those electrograms are the ones most prone to inaccurate automatic annotation of the local activation time.

Maps made with multielectrode PentaRay catheters can significantly improve the resolution of substrate scar mapping. Those catheters have smaller electrodes and closer interelectrode spacing (as compared to ablation catheters), which allow for recording bipolar signals from smaller tissue diameters that are less vulnerable to averaging and cancellation effects and, hence, more sensitive in detecting surviving myocardial fibers in low-voltage zones.²³

Propagation Map

Propagation of electrical activation can be superimposed on the 3-D anatomical reconstruction of the RA or LA, thereby allowing visualization of the reentrant circuit of AT in relation to the anatomical and EP landmarks and barriers (see eFig. 13.2). Analysis of the propagation map may allow estimation of the conduction velocity along the reentrant circuit and identification of areas of slow conduction and may thus help locate appropriate sites for entrainment mapping and catheter ablation.

Tachycardia Transformation

It is very important to ensure that the correct AT is being mapped at all points of time, and to remain vigilant to identify any change in the TCL or activation sequence that can result from catheter manipulation, pacing maneuvers, or ablation (eFig. 13.3). Such changes can indicate transition to another tachycardia requiring reassessment. The transition may be obvious, but it is often quite subtle and sometimes imperceptible if only the CS activation is analyzed. Simultaneous recording of RA activation (using a Halo catheter around the tricuspid annulus) and CS activation (using a decapolar catheter) can help in rapid identification of tachycardia transformation. However, it is also necessary to ensure that the change of activation sequence is not secondary to unintentional movement of the recording catheters.

Variations in the CL during MRAT can suggest variations in activation pathways resulting from circuit transformation or simply changes in conduction time; the latter usually manifests as CL alternans. The absence of ECG alterations accompanying changes in activation sequences

can occur because of an insufficient change in electromotive force, because of distance from the recording electrodes, or because of insufficient electrically active tissue. TCL variation can, in some cases, facilitate activation mapping by revealing when electrograms “lead” versus “follow.”

MRATs with multiple loops or those determined by functional lines of block are more prone to transformation. A single-loop tachycardia with a fixed barrier as its core typically remains stable and unchanged during catheter manipulation, and it may even be difficult to pace-terminate, although mechanical “bump” terminations rendering the tachycardia noninducible suggests mechanical stimulation close to a restricted and relatively fragile isthmus.

A change in ECG morphology without a change in the TCL can occur secondary to transformation of a multiple-loop tachycardia by interruption of one loop, a change in bystander activation sufficient to be visible on the surface ECG (typified by the change in CS and LA activation observed during incomplete ablation of the CTI in typical counterclockwise AFL), a change from tachycardia in one atrium to that in the other, or activation of the same circuit in the opposite direction (the last is possible only if the first AT stops at least transiently).

Limitation of the Use of Electroanatomic Mapping

The sequential data acquisition required for creation of the electroanatomic map remains time-consuming because the process requires tagging many points, depending on the spatial details needed to analyze a given arrhythmia. Furthermore, because the acquired data are not coherent in time, multiple beats are required, and stable, sustained, or frequently repetitive arrhythmia is usually needed for creation of the activation map. Also, variation of the TCL by more than 10% can potentially prevent complete understanding of the circuit and limit the confidence in the electroanatomic map.

Another difficulty with current technologies is that incorrect assignment of activation for even a small number of electrograms at a few points can invalidate the entire activation map; manual adjustment is often required to achieve the optimal representation. This is especially important when activation timing for the low-amplitude, highly fractionated electrograms, similar to those commonly recorded at the isthmus of macroreentrant circuits, is erroneously assigned, which can potentially result in misleading maps.

Data interpolation between mapped points is also used to improve the quality of the display; however, areas of unmapped myocardium are then assigned simple estimates of timing and voltage information, based on surrounding sampled points, which may not be accurate.

Furthermore, the patient or intracardiac reference catheter can move, thus necessitating remapping. Although a shadow (to record original position) can be placed over this catheter to recognize displacement during the procedure, in which case the catheter can be returned to its original location, this may not always be feasible or accurate.

Entrainment Mapping

Entrainment mapping provides information about sites of the RA or LA that are part of the reentrant circuit, those that are outside the circuit, and the critical isthmus of the circuit. However, before attempting to use entrainment methods for mapping, it is necessary first to demonstrate that the tachycardia can, in fact, be entrained, thus providing strong evidence that it is caused by reentry rather than by triggered activity or automaticity. At sites of entrainment, there should be confirmation of consistent capture of the atrium at the PCL for several beats, with minimal or no change in the surface morphology or intracardiac electrograms, and continuation of the identical tachycardia after cessation of pacing. Evaluation of the PPI or other criteria can be very misleading when the presence of true entrainment has not been established. In addition, it is important to verify the absence of termination and

eFig. 13.3 Tachycardia Transformation. A change in atrial activation sequence is observed during right atrial ablation during macroreentrant atrial tachycardia that interrupts one circuit while another (left atrial) circuit persists (note coronary sinus activation from distal to proximal throughout *[arrows]*). *Abl_{dist}*, Distal ablation site; *Abl_{prox}*, proximal ablation site; *CS*, coronary sinus; *CS_{dist}*, distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *His_{dist}*, distal His bundle; *His_{prox}*, proximal His bundle; *TA_{dist}*, distal tricuspid annulus; *TA_{prox}*, proximal tricuspid annulus.

BOX 13.2 Entrainment Mapping of Macroreentrant Atrial Tachycardia

Pacing From Sites *Outside* the AT Circuit Results in Manifest Entrainment

1. Manifest atrial fusion on surface ECG and intracardiac recordings (fixed fusion at a single PCL and progressive fusion on progressively shorter PCLs). Any change in atrial activation sequence, compared with baseline tachycardia and that of pure pacing, as determined by analysis of all available surface and intracardiac ECG recordings, is considered to represent manifest fusion.
2. PPI–TCL > 20 ms
3. The interval between the stimulus artifact and the onset of the P wave on the surface ECG is longer than the interval between the local electrogram on the pacing site and the onset of the P wave on the surface ECG

Pacing From Sites *Inside* the AT Circuit Results in Manifest Entrainment

1. Manifest atrial fusion on the surface ECG and intracardiac recordings (fixed fusion at a single PCL and progressive fusion on progressively shorter PCLs)
2. PPI–TCL < 20 ms
3. The interval between the stimulus artifact and the onset of the P wave on the surface ECG equals the interval between the local electrogram on the pacing site and the onset of the P wave on the surface ECG

Pacing From a *Protected Isthmus* Inside the Circuit Results in Concealed Entrainment

1. Concealed atrial fusion (i.e., paced atrial waveform on the surface ECG and intracardiac recordings is identical to the tachycardia waveform)
2. PPI–TCL < 20 ms
3. The interval between the stimulus artifact and the onset of the P wave on the surface ECG equals the interval between the local electrogram on the pacing site and the onset of the P wave on the surface ECG

AT, Atrial tachycardia; CL, cycle length; ECG, electrocardiogram; PCL, pacing cycle length; PPI, postpacing interval; TCL, tachycardia cycle length.

reinitiation of the tachycardia during the same pacing drive. Once the presence of entrainment is verified, several criteria can be used to indicate the relation of the pacing site to the reentrant circuit (Box 13.2).¹⁹

Postpacing Interval

The PPI is the interval from the last pacing stimulus that entrained the tachycardia to the next recorded electrogram *at the pacing site*. The PPI should be measured to the *near-field* potential that indicates depolarization of tissue at the pacing site that was actually captured. The PPI represents the time for the wavefront to travel from the pacing site to the reentry circuit, then to revolve around the circuit (following the same path as the tachycardia reentry wavefronts), and finally to return from the circuit to the pacing site. Thus the PPI should equal the TCL (representing one complete revolution through the reentry circuit) plus the time required for the stimulus to propagate from the pacing site to the tachycardia circuit and back to the pacing site. Given that the TCL is stable (which is a prerequisite for entrainment mapping), and that there is no decremental conduction between the pacing site and the reentry circuit, the PPI should remain relatively stable when entrainment of MRAT is performed at the same site, regardless of the length of the pacing drive or CL of pacing over a moderate range.

The greater the difference is between the PPI and the TCL (PPI–TCL), the longer the conduction time will be between the pacing site and the reentry circuit, and the greater the physical (or electrical) distance will be between the pacing site and the circuit (see Fig. 13.7; see Fig. 12.12).

The PPI–TCL value is highly reproducible during repeated entrainment attempts at the same PCL.^{19,29}

Several factors have to be considered when evaluating the PPI. The PPI should be measured to the near-field potential that indicates depolarization of tissue *at the pacing site*. However, assessment of the PPI can be problematic when the electrograms from the pacing site are not discernible, especially in regions of scar, where local near-field potentials are small and often difficult to distinguish or separate from far-field potentials. In addition, recordings of local activation at the pacing site may not be obtainable or interpretable due to electrical noise and signal saturation after the stimulus artifact. In these situations, the PPI can be measured from electrograms recorded by electrodes adjacent to those used for pacing (e.g., the proximal electrodes on the mapping catheter), but this does introduce potential error, particularly in regions of abnormal conduction.²⁰

It is important to recognize that the (PPI–TCL) value can be misleadingly long despite pacing from sites within the reentrant circuit. In one report in patients with typical AFL, long (PPI–TCL) values (more than 30 milliseconds) after entrainment from the CTI were observed in 18% of patients despite a PCL within 20 milliseconds of the TCL, and more frequently when the PCL was more than 30 milliseconds shorter than the TCL and in patients on amiodarone therapy. The long (PPI–TCL) values are likely caused by rate-dependent slowing of conduction or alterations of the activation path. These findings likely also apply to other macroreentrant tachycardias.^{30,31}

In summary, the (PPI–TCL) value serves as an approximate measure of the distance from the pacing site to the reentry circuit. During pacing at a site that is in the circuit, the conduction time between the pacing site and the circuit is 0, and the PPI equals the TCL, provided that three fundamental assumptions are true. First, pacing must capture and entrain the tachycardia. Second, the electrograms used for measurement of the PPI are recorded at the pacing site. Third, conduction through the reentry circuit must not be slowed or altered by pacing.^{31,32}

Number of Pacing Stimuli Needed to Entrain

The number needed to entrain assesses the number of captured pacing stimuli required to accelerate tachycardia to the PCL. Recording electrograms from the lateral RA and distal CS and properly timed initiation of the entrainment pacing (the coupling interval of the first paced stimulus is identical to the PCL) are required to measure the number needed to entrain. A small number (≤ 2) of pacing stimuli needed to entrain the tachycardia (with a PCL of 5 to 30 milliseconds shorter than the TCL) is consistent with a PPI–TCL value of less than 20 milliseconds and indicates that the pacing site is within the reentry circuit. A larger number of pacing stimuli needed to entrain (> 3 for PCLs of 16 to 50 milliseconds, and > 4 for PCLs of 5 to 15 milliseconds shorter than the TCL) indicates that the pacing site is outside the reentry circuit.

An advantage of this criterion is that it does not require continuation of tachycardia after pacing for assessment and remains valid even when the tachycardia terminates or changes. The number needed to entrain is also useful when electrograms for assessment of the PPI are difficult to define. Also, the number needed to entrain does not increase at shorter PCLs, likely because the conduction velocity in the intervening myocardium (between the pacing site and the reentry circuit) is less susceptible to changes in the PCL. This is in contrast to the slow conduction zone within the reentry circuit, which can display decremental conduction properties at PCLs shorter than the TCL, resulting in misleading long PPIs.³³

Conduction Time From the Pacing Site to the Circuit Exit Site

Comparing the stimulus-exit interval with the electrogram-exit interval can help identify the critical isthmus of the reentry circuit. During

entrainment of MRAT, the interval between the pacing stimulus and the onset of the P wave on the surface ECG reflects conduction time from the pacing site to the exit of the reentrant circuit (stimulus-exit interval), regardless of whether the pacing site is inside or outside the reentrant circuit, because activation starts at the pacing site and propagates in sequence to the circuit exit site. On the other hand, during tachycardia, the interval between the local electrogram at a given site and the circuit exit (electrogram-exit interval) can reflect the true conduction time between those two sites if they are activated in sequence (which occurs when that particular site is located within the reentrant pathway), or can be shorter than the true conduction time (i.e., a “pseudo-interval” that does not represent a true conduction time between the two locations) if those two sites are activated in parallel (which occurs when that particular site is located outside the reentrant circuit). Because it is frequently difficult to determine the onset of the P wave on the surface ECG, a reference intracardiac electrogram representing the exit of the circuit is usually used.

Because a diastolic electrogram is not specific for the isthmus and can be recorded from bystander sites, comparing the stimulus-exit interval during entrainment to the electrogram-exit interval (measured at the pacing site) during tachycardia can help distinguish the isthmus sites from attached bystander and inner loop sites. Activation from isthmus sites to the exit of the circuit follows the same pathway during both tachycardia and entrainment. In contrast, attached bystander and inner loop sites are activated in parallel with the exit site during tachycardia but in sequence during entrainment, resulting in a significantly shorter (more than 20 milliseconds) electrogram-exit interval than stimulus-exit interval. On the other hand, at any given pacing site, an electrogram-exit interval that is equal (± 20 milliseconds) to the stimulus-exit interval indicates that the pacing site lies within the reentry circuit and excludes the possibility that the site is a dead-end pathway attached to the circuit (i.e., not a bystander) (see Box 13.2).^{19,34}

This criterion is of value in verifying the relationship of pacing sites demonstrating entrainment with concealed fusion to the reentry circuit. This measurement can produce conflicting results in cases of manifest ECG fusion or when the onset of the surface P wave is not discernable. Therefore this criterion is of little value at pacing sites not exhibiting concealed fusion.²¹ This pitfall can be mitigated by measuring the interval between the last stimulus entraining the tachycardia and a timing reference during the second beat after the stimulus (the N + 1 beat) and then subtracting this interval from a comparable interval between the electrogram (at the pacing site) in any following beat (the so-called N + 1 difference).

Localization of the Reentry Circuit

The difference between the PPI and TCL can qualitatively estimate how far the reentrant circuit is from the pacing site. As noted, the (PPI–TCL) difference represents the conduction time from the pacing site to the reentry circuit and back. Hence, the greater the (PPI–TCL) difference, the longer the conduction time is between the pacing site and reentry circuit, and the greater the physical distance is between the pacing site and circuit. On the other hand, small (PPI–TCL) differences (<20 milliseconds) indicate that the pacing site is within or very close to the reentry circuit.

At the beginning of the mapping procedure, to quickly approximate the region of the MRAT, pacing is initially performed from the CTI, high RA, midlateral RA, and proximal and distal CS. A difference between the PPI and TCL of more than 40 milliseconds at three or more different points in the RA (including the CTI and RA free wall, but excluding the septum and CS) denotes an LA circuit.

Furthermore, during entrainment from the high lateral RA, a PPI–TCL difference of more than 50 milliseconds strongly suggests LA macro-

Fig. 13.12 Stepwise Algorithm for Determining the Location of Macroreentrant Atrial Tachycardia (AT) Circuit. See text for discussion. AFL, Atrial flutter; CS, coronary sinus; LPV, left pulmonary vein; PPI, postpacing interval; RA, right atrium; RPV, right pulmonary vein; TCL, tachycardia cycle length. (From Miyazaki H, Stevenson WG, Stephenson K, et al. Entrainment mapping for rapid distinction of left and right atrial tachycardias. *Heart Rhythm*. 2006;3, 516–523, with permission.)

reentry (Fig. 13.12). Exceptions do occur with RA scars, likely due to the potential for a long conduction time between the high RA and a circuit on the other side of a region of conduction block in the low RA. Entrainment from the low RA should identify these circuits. For RA MRATs, a (PPI–TCL) difference of less than 50 milliseconds at the proximal CS distinguishes typical AFL from a lateral RA MRAT. For LA MRATs, a (PPI–TCL) difference of less than 50 milliseconds at the proximal and distal CS distinguished perimitral MRAT from circuits involving the right PVs and septum. When entrainment does not localize the circuit in the LA or RA, a focal or small reentrant arrhythmia should be considered.³⁴ Dual- and multiple-loop reentry should be considered when entrainment mapping (analysis of the PPI) reveals large and disparate regions of the atrium being part of the circuit.

Identification of the Critical Isthmus

For identification of the critical isthmus of the reentrant circuit, entrainment mapping is performed at selected atrial sites identified during activation mapping and propagation mapping in relation to atrial scars, barriers, and lines of block. Entrainment with concealed fusion should be sought first, which indicates that the pacing site is in a protected isthmus located within or attached to the reentrant circuit. Whether this protected isthmus is crucial to the reentrant circuit or is just a bystander site needs to be verified by comparing the PPI with the TCL and the stimulus-exit interval with the electrogram-exit interval, as outlined in Box 13.2.^{19,34}

Color-Coded Mapping of Postpacing Intervals

A graphical representation of entrainment mapping can be constructed by plotting the values of the (PPI–TCL) differences on an electroanatomic mapping system to generate color-coded 3-D entrainment maps. This approach can potentially help accurately determine and visualize the 3-D location of the entire reentrant circuit, even though the area of slow conduction of the tachycardia is not described. Because none of the available electroanatomic mapping systems contains an algorithm for color-coding of entrainment information, the modus for activation

mapping is altered manually. At each 3-D location of the catheter tip stored on the electroanatomic mapping system, entrainment stimulation is performed, and the (PPI–TCL) difference is calculated and entered into the mapping system as if it were an “activation time.” For this purpose, the actual local electrogram stored at the 3-D location is completely disregarded. The annotation marker is manually moved into a position where the numerical timing information equaled the entrainment information (PPI–TCL). That timing information is then displayed in a color-coded fashion as if it were an activation time, but, in fact, it represents information on the length of the entrainment return cycle. With the color range, red (in CARTO) or white (in NavX) represents points closest to the reentrant circuit (i.e., sites with smaller [PPI–TCL] differences, approaching 0, signifying their inclusion in the reentrant circuit), and purple represents points far away from the circuit (i.e., sites with the largest [PPI–TCL] differences).^{35,36}

Color-coded 3-D entrainment mapping allows determination of the full active reentrant circuit (vs. passively activated regions of the chamber) and the obstacle around which the tachycardia is circulating, and it provides very useful information on the location of potential ablation sites. However, ablation will not terminate reentry at all of these sites; the final choice is determined by location of anatomical barriers and width of putative isthmuses, so that strategic ablation lines, mainly connecting to anatomical barriers, can be applied to transect the circuit and eliminate the arrhythmia.^{35,36}

Limitations of Entrainment Mapping

Entrainment techniques can be difficult in patients with incisional AT caused by low-amplitude or absent atrial potentials in the area of surgical incisions. The complexity and low amplitude of the electrograms within circuit isthmuses can make it impossible to reliably measure local PPIs. Furthermore, it can be difficult to consistently capture the atrium during pacing at sites of low-amplitude signals.¹⁷

Fusion during entrainment is difficult to assess on the surface ECG because the pacing artifact and QRS complex frequently obscure the surface P waves, which often have low amplitude in these patients. Furthermore, methodological problems can affect the validity of the PPI. Decremental conduction during pacing increases the PPI and causes false-negative assessment results at some reentry circuit sites. The occasional presence of far-field potentials can also impair the accuracy of entrainment mapping.

Spontaneous variations of the TCL severely compromise use of entrainment mapping, which assumes that the (PPI–TCL) differences result only from the proximity of the pacing site to the circuit and not from variable conduction velocity to, from, or within the circuit. Furthermore, it can be difficult to identify exact catheter positions in relation to anatomical barriers because visualization of these barriers is not possible fluoroscopically. Combining entrainment mapping with electroanatomic mapping can reduce the difficulties created by some of these limitations.

Importantly, overdrive pacing can potentially result in termination or transformation of the clinical tachycardia to another morphology or to AF, especially in the setting of AT with greater CL variability. Therefore it is advisable to begin with electroanatomic mapping, while pacing maneuvers are used sparingly, just to confirm the participation of precise areas in the reentry circuit and to improve understanding of the tachycardia further.^{19,34} The risk of tachycardia alteration or termination can be minimized by synchronized pacing at a PCL slightly (within 20 milliseconds) shorter than the TCL.³⁷

Noncontact Mapping

When AT is short-lived or cannot be reproducibly initiated, simultaneous multisite data acquisition using the noncontact mapping system

(EnSite 3000, St. Jude Medical, Inc., St. Paul, MN) can help map the AT circuit. This system can re-create the endocardial activation sequence from simultaneously acquired multiple data points over a few tachycardia beats without requiring sequential point-to-point acquisitions.

The EnSite 3000 system requires a 9 Fr multielectrode array and a 7 Fr mapping-ablation catheter. To create a map, the balloon catheter is positioned over a 0.035-inch guidewire under fluoroscopic guidance in the cardiac chamber of interest. The balloon is then deployed, and it can be filled with a mixture of contrast and saline to be visualized fluoroscopically. The balloon is positioned in the center of the atrium and does not come into physical contact with the atrial walls being mapped. The position of the array in the chamber must be secured to avoid significant movement that would invalidate the electrical and anatomical information. The array must be positioned as closely as possible (and in direct line of sight through the blood pool) to the endocardial surface being mapped because the accuracy of the map is sensitive to the distance between the center of the balloon and the endocardium being mapped.³⁸

Systemic anticoagulation is critical to avoid thromboembolic complications. Intravenous heparin is usually given to maintain the activated clotting time at 250 to 300 seconds and 300 to 350 seconds for RA and LA mapping, respectively.

A conventional deflectable mapping-ablation catheter is also positioned in the chamber and used to collect geometry information. The mapping catheter is initially moved to known anatomical locations (IVC, SVC, CS, HB, and tricuspid annulus for RA mapping and mitral annulus and PVs for LA mapping), which are tagged. Subsequently, detailed geometry of the chamber is reconstructed by moving the mapping catheter around the atrium. Using this information, the computer creates a model, called a convex hull, of the chamber during diastole.

Once chamber geometry has been delineated, tachycardia is induced, and mapping can begin. The data acquisition process is performed automatically by the system, and all data for the entire chamber are acquired simultaneously. The system then reconstructs more than 3000 unipolar electrograms simultaneously and superimposes them onto the virtual endocardium, to produce color-coded isopotential maps that graphically depict depolarized regions. Activation can be tracked on the isopotential map throughout the tachycardia cycle, and wavefront propagation can be displayed as a user-controlled 3-D “movie.” The color range represents voltage or timing of onset. A default high-pass filter setting of 2 Hz is used to preserve components of slow conduction on the isopotential map. When conduction through gaps in a line of block is suspected of being very slow, the high-pass filter may be set at 1.0 to 0.5 Hz. Color settings are adjusted so that the color range matches 1 to 1 with the millivolt range of the electrogram deflection of interest. Isochronal maps can also be created that represent progression of activation throughout the chamber relative to a user-defined electrical reference timing point. If the atrial electrograms overlap with the T wave, a ventricular extrastimulus may be delivered to accelerate ventricular depolarization and repolarization and reveal the following atrial complex without far-field interference.³⁸

In addition, the system can simultaneously display as many as 32 electrograms as waveforms. Unipolar or bipolar electrograms (virtual electrograms) can be selected (at any given interval of the tachycardia cycle) by using the mouse from any part of the created geometry and displayed as waveforms as if from point, array, or plaque electrodes. The reconstructed electrograms are subject to the same electrical principles as contact catheter electrograms because they contain far-field electrical information from the surrounding endocardium, as well as the underlying myocardial signal vector, and distance from the point where the signal is generated to the array can affect the contribution

to the electrogram. The maps can be particularly useful for identifying slowly conducting pathways, such as the critical slow pathways and rapid breakthrough points of MRAT. The reentry circuit can be fully identified, along with other aspects such as the slowing, narrowing, and splitting of activation wavefronts in the isthmus. The locator technology used to collect the geometry information for the convex hull can then be used to guide an ablation catheter to the proper location in the heart. Ablation lesions can be tagged, thus facilitating the performance of linear ablation devoid of gaps across the tachycardia critical isthmus.³⁸

Substrate mapping based on scar or diseased tissue, which has been introduced into noncontact mapping technology, can be of value in mapping and ablation of MRAT. Dynamic substrate mapping allows the creation of voltage maps from a single cardiac cycle and can identify low-voltage areas, as well as fixed and functional block, on the virtual endocardium through noncontact methodology. High-density voltage mapping of the atrial substrate is performed using the peak negative voltage of the reconstructed unipolar electrograms. An atrial substrate characterized by an abnormally low peak negative voltage (<30% of the maximal peak negative voltage) can potentially predict the slow conduction path within the protected isthmus of the MRAT. When combined with the activation sequence, substrate mapping provides essential information for guiding ablation, even when the arrhythmia is nonsustained.³⁹

Limitations of Noncontact Mapping

Very low-amplitude signals may not be detected, particularly if the distance between the center of the balloon catheter and the endocardial surface exceeds 40 mm or at the regions near the catheter poles, thus limiting the accurate identification of diastolic signals. In addition, the acquired geometry in the current version of the software is somewhat distorted, and multiple set points are required to clearly establish the origin and shape of complicated structures, such as the LA appendage or PVs. Otherwise, these structures may be lost in the interpolation among several neighboring points. A second catheter is still required for more detailed mapping to find the precise site to ablate, and sometimes it is difficult to manipulate an ablation catheter around the outside of the balloon, especially during mapping in the LA. Moreover, aggressive anticoagulation is required when using this system, and special attention and care are necessary during placement of the large balloon electrode in a nondilated atrium.

Practical Approach to Mapping Macroreentrant Atrial Tachycardia

Exclusion of Cavotricuspid Isthmus Dependence

Because CTI-dependent typical AFL is the most common MRAT, even in patients with prior atrial ablation or cardiac surgery, exclusion of the CTI as part of the reentrant circuit is an important initial step. This remains an important step even when the ECG pattern is not classic for counterclockwise or clockwise typical AFL. In fact, typical AFL frequently manifests with an atypical 12-lead ECG appearance (so-called pseudo-atypical flutter) in the setting of markedly abnormal atrial substrate. Typical AFL can be rapidly diagnosed or excluded by mapping of the tricuspid annulus and by entrainment maneuvers at the CTI.

Exclusion of the CTI as part of the reentrant circuit can be established by any of the following: (1) demonstration of bidirectional activation of the CTI during AT, with resulting collision or fusion within the isthmus by activation from opposing directions (the low lateral RA and CS; see Fig. 13.4); (2) recording of double potentials separated by an isoelectric and constant interval throughout the full extent of the CTI during tachycardia (indicating complete CTI conduction block); or (3) entrainment mapping from the CTI that demonstrates manifest atrial fusion with a long PPI (see Fig. 13.7).

Localization of the Reentrant Circuit Chamber (Right Versus Left Atrium)

Patient history. A history of prior surgery or ablation within a particular atrial chamber should focus the intensity of the search for the arrhythmia substrate in that chamber. MRATs can involve anatomical structures to create single- or multiple-loop or circuit reentry. In the setting of previous cardiac surgery, a right-sided location of the arrhythmia is more likely and is often seen years later in patients who had a right lateral atriotomy and who underwent surgical closure of an atrial or ventricular septal defect or valve repair. These arrhythmias can also be seen after more complex surgical correction of congenital heart disease, such as the Mustard or Senning correction of transposition of the great vessels, and also after tricuspid valve surgery. LA macroreentry is more likely in the presence of left heart disease, such as cardiomyopathy or mitral valve disease, and following catheter or surgical ablation of AF. In these patients, spontaneous conduction abnormalities and areas of electrical silence forming the substrate for arrhythmia have been observed.

Electrocardiographic findings. Lead V₁ is the most useful for distinguishing LA from RA origin. In the absence of previous cardiac surgery or catheter ablation (particularly involving linear lesions in the LA), P waves that are completely negative in lead V₁ are more frequently associated with RA free-wall circuits. Conversely, in the absence of counterclockwise typical AFL, broad-based upright P waves in lead V₁ are more frequently associated with LA circuits. A decreased amplitude of the P waves in the inferior leads is suggestive of LA origin of MRAT. LA circuits frequently generate low-amplitude P waves, with some of them having visible waves only in lead V₁.⁸ For ATs post AF ablation, negative P waves in any of the precordial leads favors RA MRAT over LA MRAT with a sensitivity and specificity of 83% and 100%, respectively, and an accuracy of 98%.¹⁵

TCL variations. Large spontaneous variations (30 to 125 milliseconds) or even 2:1 conduction in the RA CL with concomitant variations of less than 20 milliseconds in CS recordings is consistent with an LA origin of the macroreentrant circuit (see Fig. 13.5).

Activation sequence in the CS. CS activation usually propagates in a proximal-to-distal direction in the setting of RA MRATs and in a distal-to-proximal direction in the setting of LA MRATs. However, this is not always true; MRATs localized to the superior RA can result in distal-to-proximal CS activation, and a very distally positioned CS catheter can show a distal-to-proximal activation sequence with almost any RA tachycardia with RA-LA conduction over the Bachmann bundle. Some LA MRATs (e.g., counterclockwise perimitral MRAT) can activate the CS in a proximal-to-distal direction (see Fig. 13.4).⁴⁰

Activation mapping. When activation timing from 10 roughly evenly distributed sites in the RA, including three or four points at the tricuspid annulus, spans less than 50% of the TCL (in the absence of extensive RA scarring or prior CTI ablation), the arrhythmia is probably not located in the RA. In the setting of LA MRATs, RA mapping typically shows a nonreentrant activation pattern with early RA septal activation relative to other parts of the RA when LA recordings are not obtained (see Fig. 13.4).

Entrainment mapping. If macroreentry has been demonstrated, a difference between the PPI and TCL of more than 40 milliseconds at three or more different points in the RA (including the CTI and RA free wall, but excluding the septum and CS) denotes an LA circuit. In the absence of significant conduction delay within the RA, entrainment from the high lateral RA with a PPI–TCL difference of more than 50 milliseconds strongly suggests an LA macroreentry.³⁴

Identification of Barriers and Potential Lines of Block

Identification of the tachycardia circuit barriers is very important in understanding the propagation of the reentrant activation wavefront in relation to these barriers, identifying potential slow-conducting pathways critical to the reentrant circuit, identifying sites to target by entrainment mapping, and planning subsequent ablation strategy to abolish the tachycardia. Electroanatomic 3-D mapping is typically used to facilitate tagging of these anatomical and EP landmarks, rapid visualization of the activation wavefront in the context of the relevant anatomy, and performance of voltage mapping to define areas of electrical scars.

For RA macroreentry, the tricuspid annulus often provides one important barrier. Other naturally fixed barriers include the IVC, SVC, and CS os. For LA macroreentry, the mitral annulus and PVs often provide important barriers. Acquired barriers include surgical incisions or patches, surgical or catheter ablation lines, and atrial regions devoid of electrical activity (electrical scars, defined as having an atrial potential amplitude of <0.05 mV and the absence of atrial capture at 20 mA). A line of block can be identified by the presence of double potentials, thus reflecting conduction up one side of the barrier and down the other side, with the bipolar electrogram recording both waves of activation (see Figs. 14.1 and 14.2).

Identification of the Complete Reentrant Circuit

Electroanatomic activation mapping. Activation mapping is performed to define the atrial activation sequence. Reasonable numbers of points homogeneously distributed in the atrium of origin of the tachycardia must be recorded. Unlike in mapping focal AT, in which tracking the site with the earliest presystolic local activation timing is the goal of mapping, there is no early or late region for MRAT because the wavefront is continuously propagating around the circuit. The complete reentrant circuit is the spatially shortest route of unidirectional activation encompassing the complete CL of the tachycardia in terms of activation timing and returning to the site of earliest activation. Using electroanatomic mapping, this translates into continuous progression of colors (from red to purple in the CARTO system and from white to purple in the NavX system) around the atrium, with close proximity of earliest and latest local activation. In addition, propagation of electrical activation superimposed on the 3-D anatomical reconstruction of the atrium can be visualized as a propagation map in relation to the anatomical and EP landmarks and barriers (see eFig. 13.2). If comprehensive biatrial activation mapping does not cover most of the TCL, two possibilities must be considered: focal AT and small, localized reentrant circuits (i.e., electrical activity accounting for more than 85% of the TCL is present within an area with a diameter of 3 cm or less). Identification of small circuits requires much more detailed activation mapping (see Fig. 13.11).

Entrainment mapping. Entrainment mapping can be used to indicate the relation of pacing sites to the reentrant circuit, and it qualitatively estimates how far the reentrant circuit is from the pacing site (see Fig. 13.7). For RA MRAT, a (PPI–TCL) difference of less than 50 milliseconds at the proximal CS distinguishes typical AFL from a lateral RA MRAT. With LA MRAT, a (PPI–TCL) difference of less than 50 milliseconds at the proximal and distal CS distinguishes perimitral MRAT from macroreentrant circuits involving the right PVs and septum. When entrainment does not localize the circuit in the LA or RA, a focal or small reentrant arrhythmia should be considered. Color-coded 3-D entrainment mapping can facilitate determination of the full active reentrant circuit (vs. passively activated regions of the chamber) and the obstacle around which the tachycardia is circulating, and it provides very useful information on the location of potential ablation sites.³⁴

Identification of the Critical Isthmus

Electroanatomic activation mapping. Once a scar or fixed barrier is localized, its role in supporting reentry is important in determining whether the isthmuses formed around it need ablation. Whether an isthmus is a critical part of the reentrant circuit can be determined by activation mapping during sustained stable reentry and entrainment mapping. The critical isthmus may lie between two anatomical landmarks (e.g., the mitral annulus and the left inferior PV), or it can be a relatively narrow channel bounded by sites of scar or double potentials (marking lines of conduction block). Electrograms recorded within the critical isthmus frequently exhibit long, fractionated, low-amplitude potentials, likely related to very thin strands of myocardium responsible for diastolic conduction within a large scar area. During electroanatomic activation mapping, when the onset of the window of interest is set at mid-diastole between two consecutive P waves, the mid-diastolic isthmus of the reentrant circuit can potentially be identified by the interface of early and late activation (i.e., the region where “early meets late” on the color-coded activation map). High-density mapping is then performed in and around the isthmus to define its limits and width more precisely (see eFig. 13.2).

Of note, stable overdrive pacing of the critical isthmus can be difficult or impossible in RA atriotomy tachycardia because of tachycardia interruption. Isthmus participation in the circuit is often proven by tachycardia interruption with catheter pressure, as well as by tachycardia interruption and noninducibility after RF application in the area. A single, wide, fractionated electrogram can be recorded from the lower pivot point of the circuit in the low lateral RA, close to the IVC, and perhaps also from other isthmuses of the circuit. The line of double potentials or fractionated, low-voltage electrograms can also often be recorded in NSR, to allow tentative localization of the scar and the associated anatomical isthmuses.

Entrainment mapping. For identification of the critical isthmus of the reentrant circuit, entrainment mapping is performed at selected atrial sites identified during activation mapping and propagation mapping in relation to atrial scars, barriers, and lines of block. Entrainment with concealed fusion should be sought, which indicates that the pacing site is in a protected isthmus located within or attached to the reentrant circuit. Whether this protected isthmus is crucial to the reentrant circuit or is just a bystander site needs to be verified by comparing the PPI with the TCL and the stimulus-exit interval with the electrogram-exit interval, as outlined in Box 13.2.

ABLATION

In patients with MRAT, periprocedural anticoagulation management is guided by the same principle used for patients with typical AFL. In patients with persistent MRAT of a duration longer than 48 hours or unknown duration, catheter ablation should be delayed until the patient has been adequately anticoagulated at appropriate levels for 3 to 4 weeks or transesophageal echocardiography has excluded atrial thrombi. In these patients, several options exist for periprocedural anticoagulation. Traditionally, a “bridging” strategy of conversion of oral anticoagulation therapy to enoxaparin, has been employed to allow ablation and subsequent hemostasis to be performed during a pause in anticoagulation. Currently, catheter ablation has been increasingly performed while on uninterrupted periprocedural oral anticoagulation (warfarin, dabigatran, factor Xa inhibitors).

Target of Ablation

The choice of ablation sites should be among those segments of the reentry circuit that offer the most convenient and safest opportunity for creating conduction block. Among other factors are the isthmus

size, anticipated catheter stability, and risk of damage to adjacent structures (e.g., phrenic nerve, sinus node, and atrioventricular node [AVN]).

Ablation is performed by targeting the narrowest identifiable isthmus of conduction accessible within the circuit (allowing the best electrode-tissue contact along the desired line). The ablation line is chosen to transect an area critical for the circuit and, at the same time, to connect two anatomical areas of block—an electrically silent area to an anatomical zone of block (e.g., IVC, SVC, tricuspid annulus, PV, or mitral annulus), or two electrically silent areas. Voltage maps can be used to guide the choice of the ablation site. The likelihood of achieving a complete and transmural ablation line is probably greater in low-voltage zones.^{25,39}

Right Atrial Macroreentry

Lower loop reentry. Lower loop reentry is a form of CTI-dependent MRAT with a reentrant circuit around the IVC. Hence, catheter ablation of the CTI usually eliminates the arrhythmia.

Intra-isthmus reentry. This form of CTI-dependent MRAT is typically confined to the medial aspect of the CTI and the reentry circuit can be quite small. Entrainment pacing from the lateral CTI demonstrates a PPI longer than the TCL, a finding indicating that the lateral CTI is not part of the reentrant circuit. On the other hand, pacing from the region of the medial CTI or CS os demonstrates concealed entrainment with PPI equal to the TCL. Fractionated or double potentials can usually be recorded in this area and can be entrained. Although the anatomical basis of this arrhythmia remains unknown, a linear lesion across the *medial* CTI, usually at the site of a very prolonged electrogram, can cure the tachycardia. Fractionated potentials spanning one- to two-thirds of the TCL are typically recorded within the CTI. The target of ablation is a localized area within the CTI showing the longest duration of fractionated potentials associated with concealed entrainment.

Upper loop reentry. The lower turnaround point for these circuits is by conduction through a gap in functional block in the crista terminalis. Ablation in this conduction gap to complete the line of block is successful in treating this arrhythmia. It is important to exclude proximity of the phrenic nerve and, if possible, the sinus node region

to the chosen ablation site to avoid collateral damage to important structures.

Incisional RA macroreentry. Most frequently, those MRATs incorporate a circuit in the lateral RA wall around the atriotomy scar. In most cases, the lower turning point of the circuit is located between the lower edge of the scar and the orifice of the IVC, which forms the critical isthmus of the circuit. The upper turning point can be located between the end of the scar and the orifice of the SVC or around the SVC. Therefore the usual target of ablation is the isthmus between the lower end of the scar and the IVC (Fig. 13.13; see Fig. 14.2). Alternative ablation strategies include any of the following: (1) targeting the slow conduction area (critical isthmus of the reentrant circuit) as identified by detailed activation and entrainment mapping; (2) extending the scar area to the lateral aspect of the tricuspid annulus; or (3) extending the scar area to the SVC. The last approach can result in injury of the sinus node or phrenic nerve. Therefore when possible, extending the atriotomy to the IVC is preferable. In addition, because most postatriotomy MRATs are often combined with a circuit around the tricuspid annulus in a figure-eight reentry, definitive treatment should include ablation of the CTI. Even when the CTI is not involved in the MRAT circuit, it is recommended to also perform CTI ablation given the high incidence of CTI-dependent AFL in these patients.⁴²

RA macroreentry in the absence of previous surgery. These MRATs are frequently localized to the free wall of the RA and rotate around an obstacle formed by electrically silent areas. In these patients, channels with slow conduction (mid-diastolic isthmus) within the low-voltage zone can represent the mid-diastolic isthmus of the reentry circuit. Once these isthmuses are identified (by activation, entrainment, and voltage mapping), they are selectively targeted by ablation. Alternatively, linear ablation connecting the lower portion of the scar to the IVC can potentially terminate the arrhythmia. Ablation lines connecting the central scar to the SVC or to the tricuspid annulus may also be considered.

Unmappable RA macroreentrant tachycardias. In patients with incomplete maps, a combination of activation, entrainment, and voltage mapping data is used to identify the potential isthmus or zone of slow conduction critical to the reentrant circuit, which is then targeted by

Fig. 13.13 Catheter Ablation of Macroreentrant Right Atrial (RA) Tachycardia. The right posterolateral view of an electroanatomic (CARTO) map of macroreentrant RA tachycardia. (A) Activation map. (B) Bipolar voltage map demonstrates a large area of low bipolar electrogram amplitude (<0.5 mV) in the lateral RA wall at the site of prior surgery. Planning the ablation line is facilitated by correlating activation mapping findings with those of voltage mapping. Linear RF ablation (red dots) is performed to sever the isthmus between the low-voltage zone and the inferior vena cava (IVC). CS, Coronary sinus; SVC, superior vena cava.

catheter ablation. When limitations to this approach still exist (from poor inducibility or frequent change in morphology of the tachycardia), a stepwise ablation strategy may be employed. Because the reentrant circuit in most patients is anchored to the CTI or the atriotomy scar, ablation of the CTI is initially performed. Then, if the tachycardia persists, linear ablation is carried out by targeting the isthmuses related to the lateral atriotomy scar (i.e., connecting the atriotomy to the IVC, to the SVC, or to the tricuspid annulus). Additional ablation lines connecting other areas of conduction block (scar, surgical incision, septal patch, baffle, or natural barriers) may be considered based on substrate mapping findings.^{25,39}

Left Atrial Macroreentry

LA macroreentry following previous surgery. The goal is to localize the area with scar and extend this line of conduction block to an anatomical obstacle, or to transect the circuit by joining anatomical structures. Although this strategy is achievable in most of the atria, it is advisable to avoid attempting to connect the anterior septal region to the mitral annulus in the region of the low left septum because the thickness of the tissue prohibits complete lesions in approximately 40% of patients despite the use of irrigated-tip catheters. The exception to this is the presence of a narrow mid-diastolic isthmus (defined by activation, entrainment, and voltage mapping); this target is then preferable and usually much easier than longer linear lesions.⁹

LA macroreentry following ablation of AF. Knowledge of the type of initial ablation procedure is critical before embarking on AT ablation. ATs following PV isolation procedures can often be focal, typically originating from the vicinity of a reconnected PV. Most of the ATs complicating circumferential and linear LA ablations are macroreentrant, most commonly with circuits around the mitral annulus or involving the LA roof or septum. These circuits are most often related to gaps in ablation lines or to isthmuses created between the ablation lines and other obstacles in the LA. Multiple macroreentrant circuits and multiple-loop reentrant circuits are not infrequently encountered. In addition, localized reentrant circuits are not uncommon, and they usually arise from the vicinity of the isolated PVs or linear lesions.

Mapping and ablation of LA MRATs following circumferential LA ablation or circumferential PV isolation are frequently challenging. Detailed mapping with a high density of points is necessary to elucidate a more complete understanding of the activation pattern during the AT. In addition, mapping of the previously performed ablation lesions is critical to determine whether the ablation lines and PV electrical isolation are complete. When the macroreentrant circuit can be mapped, ablation lesions should be tailored to interrupt the path of the reentrant circuit (see Fig. 15.60). In the absence of complete block across the old ablation lines, the gaps must be reablated. Empirical treatment of unmappable ATs primarily involves electrical isolation of all reconnected PVs and, if needed, empirical linear lesions within the tachycardia circuit, often including a line between the mitral annulus and left inferior PV and a roof line between the superior PVs.⁴³

LA macroreentry in the absence of previous surgery or ablation. Spontaneous LA circuits have been observed. The circuits can propagate around spontaneous scars, frequently located in the posterior LA, but also around the mitral annulus or PVs. The MRAT circuit commonly depends upon a unique slow-conducting isthmus within the scar region. The critical isthmus typically exhibits long-duration fractionated electrograms and coincides with the isoelectric intervals on the 12-lead ECG. The critical isthmus, as confirmed by entrainment mapping, should be selectively targeted by ablation. Frequently, the critical isthmus is relatively narrow; 1 to 3 RF applications at the critical isthmus commonly terminate the tachycardia.¹²

Perimitral LA macroreentry. The standard approach to ablation of perimitral macroreentry involves a linear ablation lesion across the lateral mitral isthmus, connecting the mitral annulus to the ostium of the left inferior PV (eFig. 13.4). Another option is to use an anterior ablation line from the anterior mitral annulus to a region of scar (or to another ablation line in the LA roof connecting both superior PVs) through the anterior LA. Alternatively, linear ablation is performed to connect the anterior-anterolateral mitral annulus to the ostium of the left superior PV (modified anterior line; eFig. 13.5).

Roof-dependent LA macroreentry. The reentry circuit can be interrupted by linear ablation connecting the two superior PVs ("roof line").

Macroreentry around the right PVs. Circuits propagating around the right PVs demonstrate colliding wavefronts along the mitral annulus and a PPI during entrainment that is much longer at the mitral isthmus than at the roof or posterior LA. These MRATs are observed more frequently in the current approach of wide-area atrial ablation to isolate the PVs, because the lesions performed to isolate right and left PVs can potentially create a narrow isthmus in the posterior LA that then forms the substrate for MRAT. A linear lesion connecting both superior PVs through the roof is the best option. This procedure is best performed along the roof, rather than the posterior wall, to avoid the potential risk of atrioesophageal fistulas. Use of a deflectable sheath or ablation catheter with bidirectional deflection capability can facilitate this.

Macroreentry around the left PVs. Circuits around the left PVs seem rare. They can be abolished with a linear lesion joining the left inferior PV to the mitral annulus or with a roofline connecting both superior PVs.

Left septal circuits. The critical isthmus of these circuits is usually located between the septum primum and the right-sided PVs (posterior isthmus) or between the septum primum and the mitral annulus (anterior isthmus). Linear ablation across either isthmus can eliminate the tachycardia, although acute and long-term success rates remain modest. Ablation from the bilateral sides can potentially improve outcome.⁹

Unmappable LA macroreentrant tachycardias. Some LA MRATs can show some degree of variation in their CL during mapping, in which case conventional and electroanatomic mapping is less useful. Initially, in patients with prior catheter or surgical ablation for AF, all PVs need to be assessed for reconnection via the circular mapping catheter. When PV reconnection is detected, PV reisolation is performed, often requiring only a single ablation lesion. Then, an empirical strategy that commences with ablation at the mitral isthmus and the LA roof is justified because such ablation lines interrupt the most dominant circuits in the LA. Block along each line must be rigorously confirmed, as residual small gaps in the ablation line map facilitate slow reentry.

Ablation Technique

Once the ablation target is identified, ablation involves placing a series of RF lesions to sever the critical isthmus and connect two anatomical or surgical barriers. RF energy can be delivered sequentially point by point to span the targeted isthmus or by dragging the ablation catheter tip during continuous energy administration. The duration and power output of RF application is governed by the location of the ablation target and the risk of injuring neighboring structures (e.g., phrenic nerve, esophagus, AVN). Generally, an effective RF lesion is indicated by reduction of the amplitude of the bipolar electrogram by 80% or breakdown of the local electrogram into double potentials, thus indicating local conduction block. However, the documentation of electrogram breakdown into double potentials depends on the direction of activation relative to the ablation lesion and its size relative to that of the recording bipole and is maximized by activation orthogonal to the

eFig. 13.4 Posterior Mitral Isthmus Ablation Line. Segmented computed tomography (CT) of the left atrium (LA) acquired during catheter ablation of the mitral isthmus. Left lateral (A) and cardioscopic (B) views of the CT scan are shown. Small red dots are tagged sites at which radiofrequency energy was applied across the isthmus between the mitral annulus (MA) and left inferior pulmonary vein (LIPV). LAA, LA appendage; LSPV, left superior pulmonary vein.

eFig. 13.5 Modified Anterior Ablation Line for Perimitral Left Atrial Macroreentry. Three-dimensional electroanatomic (CARTO) activation map of the left atrium in the left anterior oblique (at left) and antero-superior views (at right) constructed during counterclockwise perimitral macroreentrant atrial tachycardia. Linear ablation (purple dots) connecting the anterior-anterolateral mitral annulus to the ostium of the left superior pulmonary vein (LSPV). LIPV, Left inferior pulmonary vein; MA, mitral annulus; RSPV, right superior pulmonary vein.

lesion's largest dimension. Lesion contiguity and continuity depend on ensuring the coalescence of multiple transmural lesions (facilitated by 3-D localization systems).

During delivery of RF energy, the tachycardia can terminate, or its CL can increase transiently or permanently. These findings indicate that the lesions have affected the circuit and should lead to continuation of RF delivery or extension of the lesion to ensure the achievement of complete conduction block across the isthmus. However, it is important to verify that change in the TCL is caused by slowing conduction across the critical isthmus rather than transformation of the index tachycardia into a different circuit, or simply extending a line of conduction block around which it now takes longer for the impulse to propagate.

It is not uncommon for the arrhythmia mechanism to switch rather than terminate following successful ablation. A change in atrial activation sequence or P wave morphology or a sudden change in the atrial CL may indicate that the tachycardia that was being ablated has changed to a different loop or to a different tachycardia. In this setting, it is very important to reevaluate the mechanism and location of the new arrhythmia systematically by using activation and entrainment mapping and to move to the new target if necessary. However, the transition to a different loop of a tachycardia or to a different tachycardia may occur with no discernible change in the activation sequence among the atrial electrograms that are being recorded, P wave morphology, or TCL; this is particularly true if the slower of two tachycardias is targeted and eliminated. It is important to keep this in mind when ablation across an isthmus appears not to affect the tachycardia. The isthmus may have already been blocked and may no longer be participating in the tachycardia. This should be suspected if double potentials are present along the ablation line, and it is easily confirmed by entrainment mapping near the ablation line. If that site was confirmed previously to be part of the reentrant circuit (PPI–TCL difference <20 milliseconds) and now it is outside the tachycardia circuit (PPI–TCL difference >30 milliseconds), this finding indicates that the tachycardia circuit has changed.

Endpoints of Ablation

Tachycardia Termination

Sudden termination of an incessant AT during RF application suggests that the lesion has severed a critical isthmus and that site should be targeted for additional lesions. However, reliance on AT termination during RF application as the sole criterion of a successful ablation is hazardous because such an AT can terminate spontaneously or secondary to mechanical trauma by the ablation catheter, in which case termination can be misleading. RF application itself can induce premature atrial complexes (PACs) that can then terminate AT without eliminating the substrate. In addition, RF application can cause a transient conduction delay or block in the critical isthmus, which can cause acute termination of the tachycardia; then, recovery of conduction can potentially result in later recurrences of the arrhythmia. Moreover, the sudden termination of AT can be accompanied by catheter displacement from the critical site to another site, thus making it difficult to deliver additional energy applications at the critical site.

Noninducibility of Tachycardia

To use the criterion of noninducibility of tachycardia as a reliable endpoint, careful assessment of inducibility should be performed prior to ablation. The feasibility and best method of reproducible induction of the AT should be documented at baseline before ablation, which should then be used for assessment of tachycardia inducibility after an apparently successful ablation. In the setting of easy inducibility prior to ablation, one can consider the lack of inducibility as an indicator of

successful ablation. Tachycardia inducibility should be reassessed 30 minutes after the last successful RF application.

Noninducibility of the arrhythmia is inapplicable if the original arrhythmia was noninducible at baseline, was incessant, or was inadvertently terminated mechanically. Furthermore, noninducibility may reflect conduction delay in the critical isthmus, and not stable block, or it may be secondary to changes in autonomic tone. In these situations, other procedural endpoints need to be employed.

Documentation of a Line of Block

Complete stable conduction block within the reentry path is the most useful and objective endpoint. However, achieving this endpoint can be challenging and may not be as feasible as in CTI ablation for typical AFL. Several techniques can be used to confirm complete conduction block across the ablation line:

Double potentials. The mapping catheter is used to retrace the ablation line during atrial pacing from either side of the ablation line. The demonstration of a continuous corridor of widely split double potentials recorded along the entire length of the ablation line confirms the presence of block. It is important to recognize that double potentials separated by long isoelectric intervals indicate "local block" under the recording catheter bipole, but they can be just adjacent to a conducting gap; therefore meticulous mapping of the entire length of the ablation line is necessary to exclude the presence of gaps in the ablation line and confirm the line of block. When there is a gap in a line of block, the isoelectric interval between the double potentials shortens, the closer the electrograms are to the gap. At the gap in the line of block, double potentials are no longer present, and the electrogram is typically long and fractionated, but can also be discrete. Those gaps are then targeted by additional ablation until complete block is achieved.

Atrial activation sequence. Pacing close to the ablation line and demonstration of marked delay and reversal in the direction of activation on the opposite side of the ablation line is consistent with conduction block across the ablation line, although very slow conduction can be difficult to exclude. Electroanatomic activation mapping during pacing demonstrates earliest activation at side of the ablation line ipsilateral to the pacing site, while the latest activation occurs at the contralateral side, and an early-meets-late zone along the entire length of the ablation line.

Differential pacing. Atrial pacing is performed at two separate sites on the same side of the ablation line, one site very close to the ablation line and the second site 10 to 20 mm farther from the ablation line. Local activation time is recorded on the contralateral side of the ablation line. In the presence of conduction block across the ablation line, moving the pacing site away from the ablation line shortens the conduction time to the contralateral side and shortens the distance between the double potentials straddling the ablation line. Withdrawal of the pacing site farther away from the ablation line results in a delay of the first component of the double potentials (which represents activation on the side of the ablation line ipsilateral to the pacing site). In contrast, the second component of the double potentials (which represent activation on the contralateral side of the ablation line) is activated earlier because the length of the detour around the line block that the paced wavefront must travel is shortened by the new site of pacing. As a consequence, the separation of double potentials decreases. On the other hand, in the setting of incomplete block, both components of the double potentials are the result of sequential activation by the same paced wavefront propagating across the ablation line. Therefore withdrawal of the pacing site farther away from the ablation line causes a similar degree of delay of the timing of both components of the electrogram (relative to the pacing stimulus), so that the interval between the double potentials remains constant.

Ablation of Perimitral Macroreentrant Atrial Tachycardia

The lateral mitral isthmus is short (2 to 4 cm), anatomically bounded by the mitral annulus, left inferior PV ostium, and superiorly by the LA appendage. The average thickness of the atrium along the mitral isthmus is 3.8 mm, with maximum thickness up to 7.7 mm. The CS muscle sleeve, present in up to 75% of patients, inserts into the LA inferior to the mitral isthmus and occasionally extends onto the mitral valve. Mitral isthmus ablation is performed by linear ablation to join the posterolateral mitral isthmus to the left inferior PV (posterior ablation line) (see eFig. 13.4). Alternatively, an ablation line may be deployed extending from the anterior-anterolateral mitral annulus to the left superior PV (anterior ablation line) (see eFig. 13.5).¹¹

Posterior Mitral Isthmus Ablation Line

The CS catheter is positioned to bracket the planned linear lesion between its proximal and distal bipoles. The ablation catheter is introduced into the LA through a long sheath and flexed with a 90- to 180-degree curve to achieve good contact and stability. Initially, the catheter tip is positioned at the ventricular edge of the lateral mitral annulus, where the A:V electrogram shows a 1:1 to 2:1 ratio, to begin ablation. Of note, a true annular site can be deceptively far away (toward the ventricle) from the CS catheter location (often considered to be an indicator of annular location). The sheath and catheter are then rotated clockwise and dragged gradually to extend the ablation line posteriorly, ending at the left inferior PV ostium (Fig. 13.14). In general, ablation is commenced at about the 3- or 4-o'clock position on the mitral isthmus and reaches the 2- to 3-o'clock position at the upper end of the line.⁴⁴ Because myocardial sleeves extend into the left inferior PV, electrical

isolation of this PV is frequently required to serve as a reliable anchor for the mitral isthmus ablation line.⁴⁵

RF energy is delivered with an 8-mm-tip catheter with a target temperature of 50°C to 55°C and a power of 50 to 70 W. Externally irrigated catheters are preferably used with a power of 25 to 40 W and a maximum temperature limit of 40°C to 45°C. Each RF application is extended for 90 to 120 seconds at each site. The stability of the catheter is monitored during RF applications by using electrogram recordings and intermittent fluoroscopy to exclude inadvertent displacement, which could result in high-energy delivery in the left inferior PV ostium or LA appendage.⁴⁴

When ablation is performed during NSR, the effect of each RF application is assessed on the local electrogram during pacing from the proximal bipole of the CS catheter located immediately posteromedial of the line, to maximize conduction delay. Splitting of the local potentials, with a resulting increase in the delay from the pacing artifact, is considered evidence of an effective local lesion. After the initial attempt to create this line, mapping is performed along the line to identify and ablate endocardial gaps, defined as sites showing the shortest delay between the pacing artifact and the local atrial potential, which can be single, narrow double, or fractionated.⁴⁴

Persisting epicardial conduction is suspected when the linear lesion results in adequate voltage abatement on the endocardial aspect while a large atrial potential is still recorded in the CS catheter, or when endocardial conduction delay is recorded on the ablation catheter but not on the adjacent distal bipole of the CS catheter (anterolateral to the ablation line).

Epicardial ablation within the CS is required to achieve block in more than 70% of cases (probably less with use of contact force

Fig. 13.14 Catheter Ablation of the Lateral Mitral Isthmus. Right anterior oblique (RAO; upper panels) and left anterior oblique (LAO; lower panels) fluoroscopy views of catheter placement during mitral isthmus ablation. A ring catheter (Lasso) is positioned at the ostium of the left inferior pulmonary vein. Ablation is started with the ablation catheter (Abl) at the ventricular aspect of the mitral annulus (left panel). The catheter is then moved gradually to the mid-isthmus and subsequently to the junction with the ostium of the left inferior pulmonary vein (middle panels). When the endocardial approach fails, epicardial ablation of the mitral isthmus is attempted through the coronary sinus (CS; right panel).

measurements and irrigated RF). The relatively low success rate of mitral isthmus block can be explained by several mechanisms. The shape and depth of the atrial myocardium vary greatly around the mitral isthmus, and the depth of the tissue (resulting from the double muscular layers of LA and CS) may be the limiting factor in achieving a transmural lesion by endocardial ablation alone. In addition, local cooling effects of blood flow in the circumflex coronary artery and the great cardiac vein (both pass in close proximity to the mitral isthmus) may act as a heat sink, preventing adequate tissue heating by RF delivery and making isthmus block difficult. Some investigators suggested that temporary displacement of the venous blood pool by using an air-filled CS balloon could potentially facilitate transmural mitral isthmus lesions during endocardial catheter ablation. However, studies evaluating the efficacy of this approach arrived to conflicting results, suggesting that arterial blood flow through an interposed circumflex artery may be more efficient in dissipating heat and pose a bigger challenge to ablation than the coronary venous flow.⁴⁶

When epicardial ablation is required, the ablation catheter is withdrawn from the LA and is introduced into the CS to map the epicardial side of the isthmus and identify fractionated or early potentials suggestive of an epicardial gap. The catheter is torqued toward the atrial side of the AV groove, to avoid ablation within a ventricular branch (which carries higher risk of coronary artery injury). Ablation within the CS is performed using an externally irrigated-tip catheter with a power limit of 20 to 25 W, and usually maximal flow (60 mL/min) is necessary (see Fig. 13.14). RF application should be discontinued if there is a rapid rise or fall in impedance or a rapid rise in temperature. Sometimes a power setting of 30 to 35 W is required for successful ablation. A higher power setting should be considered when a tachycardia fails to respond to ablation with 20 to 25 W and when entrainment mapping or activation mapping indicates that the CS is still an appropriate target site. A recent report described the feasibility of epicardial ablation of the mitral isthmus via the percutaneous subxiphoid approach in patients with severely symptomatic perimitral MRAT and failed endocardial and CS ablation.⁴⁷ If it appears that all electrograms in the target area have been eliminated, repeating pacing from opposite sides of the ablation line should be performed to ascertain if perimitral reentry persists, or if the ablation line is complete and the arrhythmia has changed to another form.

Anterior Mitral Isthmus Ablation Line

The ablation catheter is advanced through the transseptal sheath to the anterior-anterolateral mitral annulus, and delivery of RF lesions is started when the A/V ratio is 1:2. Linear ablation is then performed with counterclockwise rotation of the transseptal sheath and progressive release of the ablation catheter curve. The ablation line is extended just in front of (anteromedial to) the orifice of the LA appendage, and then the catheter is advanced to extend the linear lesion to the ostium of the left superior PV (see eFig. 13.5).^{47,48}

In one report, the anterior ablation line was found to be safe, feasible, and very effective, achieving tachycardia termination in 97% of cases and bidirectional block across the line in 86% of patients, without the need for RF ablation within the CS. Therefore this type of linear lesion can serve as a first-line approach for perimitral MRAT or as an alternative approach when an epicardial ablation deep within the CS is not feasible for completion of the lateral mitral isthmus ablation line.⁴⁸ Delay of activation of the LA appendage often results, with potential deleterious hemodynamic effects. In addition, if a posterior ablation line is attempted without apparent success, and the strategy is changed to an anterior ablation line, it is possible that both lines will be complete and could then effectively isolate the LA appendage electrically.

Confirmation of Mitral Isthmus Block

For perimitral MRAT, the lateral mitral isthmus is the traditional target of ablation. Mitral isthmus ablation has a well-defined demonstrable procedural endpoint of bidirectional conduction block analogous to CTI ablation. Validation of mitral isthmus conduction block is greatly facilitated by its proximity to the CS, which allows pacing and recording on either side of the ablation line to confirm bidirectional block. Several criteria are used to confirm the presence of bidirectional mitral isthmus block. The CS catheter is placed within the CS so that the distal bipole is positioned just posteromedial to the ablation line, while the mapping catheter is positioned endocardially in the LA just anterolateral to the ablation line. Alternatively, the CS catheter can be positioned to straddle the ablation line.

Double potentials. The presence of widely separated (by 150- to 300-millisecond intervals) local double potentials along the length of the ablation line during pacing from either side of the ablation line confirms the presence of block.

Atrial activation sequence. Mapping the activation detour during pacing from the posteromedial side of the line through the CS catheter demonstrates marked delay and reversal in the direction of activation at the anterolateral side of the isthmus. Pacing anterolateral to the ablation line via the ablation catheter placed endocardially demonstrates a proximal-to-distal activation sequence along the CS posteromedial side of the line, thus confirming bidirectional conduction block (Fig. 13.15). It is important to ensure that the distal bipole of the CS catheter is positioned very close to the ablation line; otherwise, a proximal-to-distal activation sequence along the CS can be interpreted as evidence of block when only conduction delay across the ablation line is present. The activation detour during complete isthmus block can also be determined using 3-D electroanatomic mapping (Fig. 13.16).⁴⁴

Differential pacing. With the distal bipole of the CS catheter placed just posteromedial to the ablation line, the pacing site is changed from the distal to the proximal bipole of the CS catheter without moving any of the catheters. The stimulus-to-electrogram timing at an LA site close to the opposite side of the ablation line is measured before and after changing the pacing site. With complete block, the stimulus-to-electrogram interval is shortened after shifting the pacing site from the distal to proximal CS bipole (Fig. 13.15; eFig. 13.6).⁴⁴

It is important to recognize that pacing and recording maneuvers for assessing mitral isthmus block are usually carried out from two different compartments (LA and CS). The venous wall of the CS is surrounded by a sleeve of atrial myocardium that extends for 25 to 51 mm from the CS os, which is continuous with the RA myocardium proximally, but it is usually separated from the LA by adipose tissue. This separation is variably bridged by muscular strands producing electrical continuity between the CS musculature and the LA. Therefore pacing within the CS can potentially capture local CS musculature but not the LA myocardium. This can result in a delay in LA activation during CS pacing given that the paced impulse has to travel via an LA-CS muscular connection that can be at a distance from the pacing site. As a consequence, delayed activation of the LA (as recorded by the mapping or ablation catheter positioned within the LA) can be misinterpreted as evidence of conduction block across the mitral isthmus ("pseudoblock") when actually no such block is present. This is also true during pacing endocardially within the LA without capturing the CS muscular sleeve. Therefore it is critical to verify that both the CS and LA are captured by the paced stimulus to avoid erroneous diagnosis. These pitfalls can be avoided by pacing (in the LA or CS) at an output high enough to ensure capture of endocardial LA, as well as the epicardial CS tissue. However, pacing at output higher than necessary can cause wide-area capture such that the site across the ablation line is stimulated simultaneously with the pacing site,

eFig. 13.6 Bidirectional Block Across the Mitral Isthmus Ablation Line. Endoscopic view of a computed tomography scan of the left side of the left atrium (LA). The orifices of the left superior pulmonary vein (LSPV) and left inferior PV (LIPV) and LA appendage (LAA) are shown. An ablation line (red shading) has been made between mitral annulus (MA, orange dashes) and the LIPV orifice to transect the mitral isthmus. A multipolar ring catheter is situated on the LA endocardium as shown; the tip of the coronary sinus (CS) catheter (situated epicardial to the LA) is proximal to the ablation line. During pacing from A (asterisk), proximal to the ablation line, the ring catheter recordings appear soon after the stimulus artifact and CS electrodes are activated from distal to proximal. Pacing from B (asterisk), distal to the ablation line, shows the ring electrodes are activated much later than before, and the CS is now activated from proximal to distal, thus indicating bidirectional block at the mitral isthmus. *Abl_{dist}*, Distal ablation site; *Abl_{prox}*, proximal ablation site; *CS_{dist}*, distal coronary sinus; *CS_{mid}*, middle coronary sinus; *CS_{prox}*, proximal coronary sinus; *His_{dist}*, distal His bundle; *His_{prox}*, proximal His bundle; *PV*, pulmonary vein.

Fig. 13.15 Verification of Bidirectional Mitral Isthmus Block. *Upper panel*, Ablation of the mitral isthmus is performed during pacing anterolateral to the ablation line (a Lasso catheter positioned at the ostium of the left inferior pulmonary vein [LIPV] is used in this case). With intact isthmus conduction, coronary sinus (CS) activation occurs through the wavefront propagating in the counterclockwise direction; thus a distal-to-proximal CS activation sequence is observed. When clockwise isthmus block is achieved, CS activation occurs through the wavefront propagating in the clockwise direction; thus reversal of the CS activation sequence is observed. The ablation catheter (ABL) is positioned at the septal aspect of the line of block. The stimulus-to-electrogram interval recorded by the ablation catheter prolongs suddenly on development of clockwise isthmus block. *Lower panels*, Differential pacing is performed from the proximal and distal CS (CS_{prox} , CS_{dist}) bipoles (both positioned at the posteromedial aspect of the ablation line) to verify the presence of counterclockwise isthmus block. In the presence of counterclockwise block, activation lateral to the ablation line (as recorded by the Lasso catheter in the LIPV) occurs through the wavefront propagating in a clockwise direction up the left atrial (LA) septal wall and over the LA roof. Consequently, LIPV activation occurs earlier during pacing from the proximal CS (*left panel*) compared with the distal CS (*right panel*). A yellow star marks the pacing site. *Continued*

Fig. 13.15, cont'd

especially when the pacing bipole is very close to or straddles the ablation line.⁴⁴

The LA appendage is frequently selected as a pacing and recording site during verification of the presence of mitral isthmus block. In the setting of the anterior ablation line, the LA appendage is located lateral to the line of ablation. However, in the setting of the posterior ablation line, the LA appendage is located anteromedial to the ablation line. In the latter setting, however, one should understand that the LA appendage is not always a reliable site for pacing anteromedial to the ablation line, because epicardial connections between the appendage and the vein of Marshall can potentially mediate conduction to the distal CS even in the presence of isthmus block.^{45,49}

Outcome

Short-term success rates are reasonably good (approximately 90% in experienced centers). However, recurrence rates of the same or other tachycardias are high; up to 59% of cases required repeat ablation in some studies. Long-term freedom from arrhythmias can be achieved in 73% to 90% of patients after multiple procedures. The best outcomes have been observed for MRATs related to surgical incisions. Acute and long-term success seem to be lower for septal circuits (likely due to the structural complexity and thickness of the interatrial septum), macroreentry related to idiopathic scar (likely related to the presence of diffuse

atrial myopathy), and in patients with multiple tachycardias.⁵⁰ Some patients undergo ablation while taking antiarrhythmic drugs such as amiodarone; when the drug is stopped after an apparently successful ablation procedure, resurgence of the same or other tachycardias can occur if the drug had been suppressing a circuit or initiators of reentry.

In patients with perimitral MRAT, bidirectional block at the lateral mitral isthmus can be acutely achieved in 65% to 92% of patients, with ablation within the CS being required in about two-thirds of patients (less than this now with more routine use of irrigated RF and contact force sensing catheters). In one report, the modified anterior line (extending from the anterior/anterolateral mitral annulus to the ostium of the left superior PV) resulted in bidirectional block across the ablation line in 86% of patients. On the other hand, a complete line of block could be achieved in only 58% when combining a roof line with an anterior line connecting the mitral annulus and the right superior PV or the septal part of the roof line.

Catheter ablation of MRATs can potentially cause significant complications, due to the extended periods of mapping and catheter manipulation, frequent need for LA access, and relatively large areas of linear ablation required in many patients. Ablation of LA MRATs can be associated with complications similar to those observed in AF ablation (see Chapter 15). For RA MRATs, complications are similar to those reported for focal ATs (see Chapter 11).⁵⁰

Fig. 13.16 Confirmation of Block Across the Ablation Line. (A) Left lateral view of three-dimensional electroanatomic (Rhythmia) activation map of the left atrium (LA). Linear ablation (posterior mitral isthmus ablation line, *purple dots*) successfully terminated perimitral LA macroreentry. The activation color map displays the activation pattern following restoration of sinus rhythm and during atrial pacing (*asterisk*) just posterior to the ablation line. Note the formation of an early-meets-late zone (*violet to red*) along the entire length of the ablation line demonstrating the achievement of a continuous conduction block. (B) Left anterior oblique view of three-dimensional (CARTO-3) activation map of the LA. Linear ablation (modified anterior mitral isthmus ablation line, *purple dots*) successfully terminated perimitral LA macroreentry. The activation color map displays the activation pattern during atrial pacing (*asterisk*) at the root of the LA appendage (LAA), just lateral to the ablation line. Note the formation of an early-meets-late zone (*violet to red*) along the entire length of the ablation line demonstrating the achievement of a continuous conduction block. Video 13.1 Clockwise and Counterclockwise Perimitral Left Atrial Macroreentry: CARTO Activation and Propagation Maps. Shown are electroanatomic (CARTO) activation and propagation maps of the left atrium during clockwise and counterclockwise perimitral macroreentrant atrial tachycardias in two different patients. *LAA*, Left atrial appendage; *LIPV*, left inferior pulmonary vein; *LSPV*, left superior pulmonary vein; *RIPV*, right inferior pulmonary vein; *RSPV*, right superior pulmonary vein.

Video 13.2 Macroreentrant Atrial Tachycardia (involving the pulmonary veins): Rhythmia Propagation, Activation, and Voltage Maps. Electroanatomic (Rhythmia) activation and propagation maps of the left atrium (LA) acquired during sustained atrial tachycardia in a patient with prior history of catheter ablation of atrial fibrillation (circumferential antral pulmonary vein [PV] isolation) and electrical isolation of the LA posterior wall (with linear ablation across the LA roof and floor). Propagation and activation maps demonstrate atrial macroreentry around the right superior PV. Local electrograms recorded at different parts of the reentry circuit are also shown. *LAA*, Left atrial appendage; *LSPV*, left superior pulmonary vein; *MA*, mitral annulus; *RIPV*, right inferior pulmonary vein; *RSPV*, right superior pulmonary vein.

Video 13.3 Incisional Right Atrial Macroreentry: CARTO Activation, Voltage, Propagation, and Ripple Maps. Electroanatomic (CARTO 3) activation, voltage, propagation, and ripple maps of the right atrium acquired during a macroreentrant right atrial tachycardia in a patient with prior atriotomy. Note large low-voltage (scar) areas in the right atrial free wall with a channel of myocardium with preserved voltage that serves as the isthmus of the macroreentrant circuit. This case demonstrates how ripple mapping better correlates the activation sequence with underlying substrate than does activation and propagation mapping. Linear ablation across the isthmus successfully eliminated the tachycardia. *CS*, Coronary sinus; *IVC*, inferior vena cava; *SVC*, superior vena cava; *TA*, tricuspid annulus.

PATHOPHYSIOLOGY

Cardiac arrhythmias are a common problem in patients with congenital heart disease (CHD), particularly after they have undergone reparative or palliative surgical procedures. Atrial tachyarrhythmias are the most prevalent, with a lifetime risk of approximately 50%, regardless of the severity of the congenital defects. Macroreentry localized to the right atrium (RA) is the most common mechanism, followed by atrial fibrillation (AF). Focal ATs are also observed, but less frequently.¹

Macroreentrant Atrial Tachycardia

For macroreentrant atrial tachycardias (MRATs) in adults with repaired CHD, three RA circuits are generally identified: (1) lateral wall circuits with reentry around or related to the lateral atriotomy scar; (2) septal circuits with reentry around an atrial septal patch; and (3) typical atrial flutter (AFL) circuits using the cavotricuspid isthmus (CTI). Peritricuspid reentry (typical clockwise or counterclockwise CTI-dependent AFL) is the most common single mechanism and usually coexists with other forms. Atrial macroreentry in the RA free wall is the most common form of non-CTI-dependent RA macroreentry. Left atrial (LA) macroreentrant circuits are infrequent in this patient population.

The complexity of the MRAT circuits depends on the underlying congenital anomaly and the complexity of the surgical repair. Very complex or multiple reentry circuits can be seen after placement of an intraatrial baffle (Mustard or Senning correction for transposition of the great vessels) in an extremely dilated RA, after a Fontan procedure, and in patients with a univentricular heart.²

Anatomical factors promoting macroreentry in patients with CHD include abnormalities of the underlying cardiac anatomy, surgically created anastomoses, and atriotomy scars, resulting in barriers to impulse propagation and protected isthmuses with adjacent anatomical structures. Conduction abnormalities can be further aggravated by atrial

dilatation and scarring secondary to persisting pressure or volume overload after cardiac surgery or because of residual septal defects, valvular abnormalities, or ventricular dysfunction. At greatest risk are patients with single ventricular physiology and Fontan circulation, atrial baffles created by Mustard and Senning procedures for treatment of D-transposition of the great arteries, and repaired tetralogy of Fallot; but patients with simple atrial septal defect repair are also vulnerable years after surgical repair.

The best characterization of MRAT caused by atriotomy is activation around an incision scar in the lateral RA wall, with a main superoinferior axis (Fig. 14.1). This is a common problem in patients who have undergone surgery for congenital or valvular heart disease. The length, location, and orientation of the atriotomy incisions, as well as potential electrical conduction gaps across the atriotomy, are important determinants of arrhythmogenicity. Not only does the central obstacle include the scar, but also functional block can magnify this obstacle to include the superior vena cava (SVC). The anterior RA wall is commonly activated superoinferiorly (descending activation pattern), as in counterclockwise typical AFL. However, the septal wall frequently lacks a clear-cut inferosuperior (ascending) activation pattern. A line of double potentials can be recorded in the lateral RA, extending superoinferiorly. Double potential separation can be more marked and demonstrate a voltage lower than in typical AFL. Narrow passages (isthmuses) in the circuit can be found between the SVC and the superior end of the atriotomy scar, between the inferior vena cava (IVC) and the inferior end of the atriotomy, between the atriotomy scar and the tricuspid annulus, between the atriotomy and the crista terminalis, or even within the scar itself (Fig. 14.2).

Typical AFL is also often associated with RA atriotomy. In fact, the single most common form of AT among patients with CHD appears to be CTI-dependent AFL, accounting for more than 70% of all MRATs, particularly in patients with simpler anatomical lesions (e.g., tetralogy

Fig. 14.1 Incisional Right Atrial Macroreentry. Electroanatomic (CARTO) activation map of macroreentrant atrial tachycardia in a patient with previous surgical repair of an atrial septal defect. Gray areas in the posterolateral right atrium represent areas of unexcitable scar related to previous atriotomy, characterized by very low-voltage electrograms. During tachycardia, the activation wavefront travels in a macroreentrant circuit around the atriotomy scar. Ablation lines (red dots) connecting the atriotomy scar to the inferior vena cava (IVC) and superior vena cava (SVC) successfully eliminated the tachycardia.

of Fallot, atrial and ventricular septal defects) (Fig. 14.3). The atriotomy scar in the lateral or posterolateral RA forms a fixed posterior barrier to conduction in the superoinferior direction between the vena cavae, a lateral boundary necessary for the development of a peritricuspid reentry (typical AFL) by preventing short-circuiting of the tricuspid annulus via the posterior atrium. Other RA MRATs involving free wall atriotomy become progressively more common with more extensive atrial incisions.³

Reentry circuits can also occur in the sinus node region, possibly as a result of injury related to the superior atrial cannulation site for the bypass pump. These circuits can be quite small, often manifesting as focal tachycardia in the sinus node region, and they frequently can be ablated in a single location without establishing a particular line of block.

More recently, ATs arising from the morphological LA (i.e., the pulmonary venous atrium) have been described after surgical repair of CHD. The incidence of those ATs is higher in patients with univentricular hearts and those with prior ipsilateral atrial surgery. The mechanism of those ATs is more heterogeneous than that arising from the morphologic RA (i.e., the systemic venous atrium). Macroreentry is a less predominant mechanism, accounting for less than 50% of cases.⁴

Focal Atrial Tachycardia

Focal mechanisms underlying postoperative AT have been rarely reported in this patient population. Nonautomatic focal ATs are predominantly found in adults, with most foci in the RA. The mechanism underlying focal AT is unknown. Both triggered and microreentrant mechanisms have been suggested. Viable myocardial fibers embedded within areas of

Fig. 14.2 Right Atrial (RA) Figure-of-8 Macroreentry. Electroanatomic (CARTO) activation map of macroreentrant atrial tachycardia in a patient with previous surgical repair of an atrial septal defect. Gray areas in the posterolateral RA represent areas of unexcitable scar related to previous atriotomy, characterized by very low-voltage electrograms. During tachycardia, the activation wavefront travels from the midposterior RA superiorly and inferiorly, and both counterclockwise and clockwise wavefronts return to the region proximal to the exit site (purple) to complete the circuit by propagating through a narrow isthmus bounded by two areas of unexcitable scar (figure-of-8 reentry). Radiofrequency ablation targeting the gap in the atriotomy scar successfully eliminated the tachycardia. IVC, Inferior vena cava; SVC, superior vena cava.

scar tissue, which play a pivotal role in the initiation and perpetuation of macroreentrant tachycardias, can also be the site of origin of a focal AT and thus play an important role in the pathogenesis of these ATs.

Atrial Fibrillation

During long-term follow-up, AF develops in more than one-third of patients with CHD. Compared with MRAT patients, those with AF tend to be older and the arrhythmia develops later after surgery. AF is frequently associated with markers of left-sided heart disease (i.e., left ventricular [LV] systolic dysfunction and LA dilation) and is most commonly seen in patients with congenital aortic stenosis, mitral valve disease, palliated single ventricles, unrepaired heart defects, or end-stage heart disease.² Compared to patients without congenital heart defects or with simple congenital heart defects, AF develops at a younger age in patients with complex congenital heart defects. Coexistence of episodes of AF and regular AT has been reported in a considerable number of patients (33%). Regular AT preceded development of AF in approximately two-thirds of patients. Approximately 30% of patients who have previously undergone successful catheter ablation for MRAT develop AF during long-term follow-up.^{5,6}

Early Postoperative Atrial Tachycardia

Arrhythmias are also frequently observed in the early postoperative period after corrective surgery in children, occurring in 14% to 48% in the first few days after surgery. The most common arrhythmia in

Fig. 14.3 Surface Electrocardiograms of Two Types of Atrial Macroreentrant Atrial Tachycardia in a Patient With Previous Surgical Repair of Atrial Septal Defect. (A) Macroreentrant circuit around the atriotomy scar. (B) Counterclockwise typical atrial flutter (AFL) that developed following successful ablation of the scar-related macroreentry. Spontaneous premature ventricular complexes allow better visualization of the P wave (flutter wave) morphology. RA, Right atrial.

this period is junctional tachycardia, occurring in 5% to 10% of the operated children and usually self-limiting. Other supraventricular arrhythmias are also seen in 4%. The occurrence of early postoperative arrhythmias seems to be related to procedural factors of cardiac surgery, which are, in turn, related to the complexity of the congenital malformation. Local inflammation, metabolic and hemodynamic stress, as well as inotropic drug therapy can potentially promote automatic and triggered activity focal atrial and junctional tachycardias. Early postoperative arrhythmias influence the long-term outcome of patients with CHD and have been found to be a predictor of late complications, such as ventricular dysfunction, late arrhythmias, and late mortality. However, whether preventing these arrhythmias will influence the long-term survival of patients with CHD is unknown.

Atrial Septal Defect

Atrial septal defects are among the most common congenital heart lesions in adults. In the absence of surgical repair, the prevalence of supraventricular arrhythmias increases with age, with typical AFL being the most common. In the presence of atriotomy incisions, sutures, or patches, non-CTI-dependent MRATs can occur or coexist with typical AFL. Common substrates include macroreentry along the lateral RA wall and double-loop or figure-of-8 circuits. The septal patch itself is rarely a critical conduction obstacle.⁷

The timing of surgical closure of the atrial septal defect appears to affect the incidence of atrial arrhythmias. Approximately 60% of patients who have undergone surgical closure at adult age (older than 40 years) continue to have atrial tachyarrhythmias (AT and AF) during follow-up after surgery. In contrast, surgical closure performed during childhood provides a substantially lower incidence of arrhythmias. The impact of transcatheter atrial septal defect closure on atrial arrhythmias is less clear. In one series, all patients with persistent arrhythmias remained in AF or AFL after closure.^{6,8}

Tetralogy of Fallot

Tetralogy of Fallot is the most common cyanotic congenital heart condition, and it accounts for approximately 10% of the adult CHD patient group. ATs occur commonly (12% to 34%) during extended follow-up after tetralogy of Fallot repair. The observed prevalence of atrial arrhythmias is modestly higher than that of ventricular arrhythmias (15%). The most common atrial circuit is typical AFL. Other circuits often involve the lateral RA wall and may be multiple, often with a double-loop type of reentry. Nonautomatic focal ATs are infrequent and most commonly arise adjacent to suture points, with radial spread of activation. The prevalence of AF increases with advancing age. In the first few decades of life, AF is far less common than MRAT, but it becomes more common (more than 30%) than MRAT after 55 years of age.⁹

Dextro-Transposition of the Great Arteries

Dextro-transposition (D-transposition) of the great arteries accounts for 5% to 7% of congenital heart defects. The Mustard and Senning procedures utilize an intraatrial baffle constructed from prosthetic material or pericardium (Mustard) or from the atrial septum and RA free wall (Senning) to redirect the venous blood from the IVC, and the IVC to the LV via the mitral valve, and the pulmonary venous blood to the RV via the tricuspid valve ("atrial switch procedure"). The "new RA" is called the systemic venous atrium and the "new LA" becomes the pulmonary venous atrium.¹⁰ Both procedures were performed from the early 1960s until approximately 1985 as the major long-term surgical palliation procedures for young children having D-transposition of the great arteries. Hence, there is a population of patients in their early 30s to late 50s who have undergone these operations and who are at an increased risk (15% to 48%) of having supraventricular arrhythmias, with similar rates in patients with Mustard and Senning baffles. Since the mid-1980s, with development of coronary artery reimplantation techniques, arterial switch surgery has supplanted atrial redirection as the procedure of choice for D-transposition of the great arteries, and it has been associated with a significantly lower risk of arrhythmias, with a reported arrhythmia-free survival rate of 97% after 25 years of follow-up.^{4,8,10,11}

The most common arrhythmia in patients after Mustard or Senning operations for transposition is atrial macroreentry, occurring in up to 30% of these patients. Typical AFL accounts for up to 75% of all MRATs, but non-CTI-dependent MRATs with critical zones of slow conduction between a suture line and the SVC orifice, mitral valve annulus, and pulmonary vein orifice have all been described. Focal ATs adjacent to suture lines are not uncommon. Importantly, the tricuspid valve is on the pulmonary venous side while the IVC is on the systemic venous side of the circulation; as a consequence, the CTI is necessarily divided between the two sides. Therefore access to the pulmonary venous atrium is almost always necessary for ablation of MRAT and typical AFL, which can be accomplished via a retrograde aortic approach through the tricuspid valve or by transbaffle puncture.^{1,11}

Univentricular Hearts With Fontan Palliation

Among patients with CHD, the incidence of MRAT is highest (up to 50% within a decade of surgery) in older patients who have had older-style palliative surgeries for univentricular hearts, typically varieties of the Fontan procedure. In the older-style Fontan (atriopulmonary [RA appendage-to-pulmonary artery] anastomosis) operations, extensive suture lines, and long-term hemodynamic stress result in marked RA dilation, hypertrophy, and fibrosis. Overall, the most common arrhythmia in these patients is typical AFL, but other MRATs as well as focal ATs are also observed. MRAT circuits in Fontan patients can be complex and multiple, and they represent the most challenging arrhythmias for mapping and ablation.^{1,12} Pericaval circuits have been identified specifically in Fontan patients. In all CTI-dependent circuits, successful ablation requires access to the pulmonary venous atrium (via a fenestration in the intracardiac baffle or a transbaffle puncture) to create the line between the tricuspid annulus and IVC.^{13,14}

The incidence of atrial tachyarrhythmias appears to be reduced by 50% to 70% in patients with total cavopulmonary connections in comparison with classical atriopulmonary connections. Newer Fontan designs (total cavopulmonary connections) bypass the RA to a large extent, using either a lateral tunnel or an extracardiac conduit, thereby avoiding RA dilation and resulting in significant reduction in MRAT incidence to 2% to 7%. In the latter group, however, the macroreentry circuits are typically located on the pulmonary venous side of the tunnel or conduit, requiring complex techniques for accessing the arrhythmia substrate (tunnel/conduit puncture). In patients who have already

developed arrhythmias and then undergo lateral caval tunnel conversion to decompress the right atrium, arrhythmias often subside after this procedure (during which various forms of maze surgery can also be performed), but in many cases, atrial arrhythmias remain problematic.^{1,7,12}

EPIDEMIOLOGY AND NATURAL HISTORY

Congenital heart defects complicate approximately 0.5% to 1% of all live births. Currently, more than 1 million adults are living with CHD in the United States and 1.8 million in Europe. This group now outnumbers children with CHD, reflecting the marked improvements in the early diagnosis and surgical and medical management of congenital heart surgery. The prevalence of atrial arrhythmias is 15% in adults with CHD; for patients with complex congenital defects, the lifetime risk of atrial arrhythmias is more than 50%.⁶

Atrial tachyarrhythmias are an important source of morbidity and mortality in this patient population. Atrial arrhythmias are associated with a 50% increase in mortality and a two-fold increased risk of heart failure or stroke.¹⁵ Approximately 50% of 20-year-olds with CHD will develop an atrial tachyarrhythmia during their lifetime. The incidence of atrial arrhythmias is highest among patients with single ventricle with a Fontan circulation (29% to 60%) and those with transposition of the great arteries after Mustard or Senning operations (14% to 48%), but atrial tachyarrhythmias remain prevalent even in patients with simple congenital defects.^{6,7}

MRAT is the most common mechanism for symptomatic tachyarrhythmias in the adult population with CHD. Surgical incisions in the RA for repair of atrial septal defects are probably the most common causes of lesion-related reentry in adults. Usually, MRAT appears many years after operations that involved an atriotomy or other surgical manipulation. This arrhythmia can infrequently follow simple procedures, such as closure of an atrial septal defect, but the incidence is highest among patients with advanced dilation, thickening, and scarring of their RA. Other risk factors for MRAT include severe myocardial dysfunction, poor hemodynamic status, concomitant sinus node dysfunction (SND), and older age at the time of cardiac surgery. It should be recognized, however, that typical AFL is more common than non-CTI-dependent MRAT, even in this population, and both macroreentry circuits often coexist in a single patient. Importantly, the development of new-onset atrial arrhythmias can be a consequence, rather than a cause, of hemodynamic deterioration.

As noted, AF develops in more than one-third of patients with CHD during long-term follow-up, and is more common in patients with severe congenital defects, residual left-sided lesions, or unrepaired heart disease. AF can coexist with MRAT, and can persist after successful ablation of MRAT.⁵ AF is rarely seen in atrial septal defect patients, before the age of 40 years, but the incidence can approach 50% in unrepaired patients beyond 60 years of age.^{6,7}

The overall prevalence of thromboembolic complications in the relatively young CHD population, with and without atrial arrhythmias, has been estimated to be 10-fold to 100-fold higher than in age-matched controls. During a follow-up period of 5 (0 to 24) years, cerebrovascular accidents occurred in 13% of patient with CHD. A higher rate was associated with the absence of sinus rhythm and in patients with cyanotic heart disease. Notably, a considerable number of cerebrovascular events occurred before the initial documented AF episodes, likely due to dilated cardiac chambers with sluggish flow, intracardiac prosthetic material, intracardiac shunts, and associated hypercoagulable states. Nevertheless, it remains unclear whether subclinical episodes of AF play a role in these events.^{5,15}

SND is not infrequent in this patient population, and can potentially hinder pharmacological therapy in patients with atrial tachyarrhythmias.

CHD, such as sinus venosus atrial septal defects and heterotaxy syndromes (particularly left atrial isomerism), can be associated with SND, even though no surgery has been performed. A more common cause of SND in patients with CHD is injury to the sinus node caused by corrective cardiac surgery. Most commonly associated with this complication is the Mustard, Senning, Glenn, and Fontan operations, as well as repair of atrial septal defects, especially of the sinus venosus type. Surgical incisions, suture lines, and cannulation of the SVC can result in direct damage to the sinus node, its blood supply, or neural inputs.¹⁵ In addition, SND may develop as a consequence of longstanding hemodynamic perturbations or the atrial arrhythmias frequently observed in this patient population.

CLINICAL PRESENTATION

MRATs are typically chronic or long-lasting, but can also be paroxysmal. As with AF and typical AFL, patients can present with symptoms related to rapid ventricular response, loss of atrial contribution to ventricular filling, tachycardia-induced cardiomyopathy, or deterioration of pre-existing cardiac disease. Although MRATs can be asymptomatic, patients typically present with a spectrum of symptoms including palpitations, dizziness, reduced activity tolerance, and dyspnea. Severe decompensation of heart failure can develop. Importantly, the onset of AT often coincides with the presence of significant hemodynamic abnormalities (e.g., worsening ventricular function, baffle obstruction or leak, or progression of valvular or conduit stenosis, or regurgitation) that precipitate or contribute to the development of arrhythmia.

Generally, in the adult population with CHD, MRATs tend to be slower than typical AFL, with atrial rates in the range of 150 to 250 per minute. In the setting of a normal atrioventricular node (AVN) function, such rates frequently conduct in a rapid 1:1 atrioventricular (AV) pattern and can potentially result in hypotension, syncope, or possibly circulatory collapse in patients with limited myocardial reserve. This phenomenon can potentially be compounded by ineffective atrial transport and ventricular dysfunction. Even if the ventricular response rate is well controlled, sustained MRAT can cause debilitating symptoms in some patients because of the loss of AV synchrony and can contribute to thromboembolic complications.

Late-onset supraventricular arrhythmias in patients with CHD can potentially have a major impact not only on morbidity but also on mortality. Rapidly conducting atrial tachyarrhythmias can potentially cause rapid hemodynamic deterioration and trigger ventricular arrhythmias (tachycardia-induced tachycardia) and sudden cardiac death in patients with systemic right ventricles and univentricular hearts.

INITIAL EVALUATION

In patients with CHD, arrhythmia onset can herald a changing hemodynamic profile and can be the first sign of deterioration. Therefore, if arrhythmias occur, a thorough evaluation of the hemodynamic status is warranted. In addition, detailed evaluation of cardiac function, and anatomy and knowledge of the congenital anomaly and previous surgical procedures, are very important. This evaluation can require trans-thoracic or transesophageal echocardiography, right or left heart catheterization, angiography of the desired cardiac chamber, and cardiovascular magnetic resonance (CMR).¹⁵

PRINCIPLES OF MANAGEMENT

AT in CHD patients can result in significant hemodynamic consequences, and prompt management is important. Management of AT should address four main issues: (1) ventricular rate control; (2) restoration

of normal sinus rhythm (NSR); (3) maintenance of NSR; and (4) prevention of systemic embolization.

Rate Control

Ventricular rate control during AT is important to prevent hemodynamic instability and improve symptoms in patients with CHD. Oral or IV AVN blockers are utilized for rate control, depending on the severity of symptoms and the degree of hemodynamic compromise caused by the tachycardia. Beta-blockers or nondihydropyridine calcium-channel blockers (verapamil and diltiazem) are the drugs of choice for rate control. Ventricular rate control, however, is often challenging and, for patients with rapid ventricular rates and hemodynamic compromise, hypotension, or acute heart failure, prompt electrical cardioversion is recommended.¹⁵

Restoration of Sinus Rhythm

Ventricular rate control during AT is usually difficult to achieve, and even with adequate rate control, a subset of patients (e.g., those with a univentricular hearts or systemic right ventricles with decreased contractility) may not tolerate prolonged periods with loss of AV synchrony. Hence, unless contraindicated, restoration and maintenance of NSR is preferred in most patients, particularly in the setting of moderate or complex CHD. Rate control strategy generally is reserved to patients with contraindication to anticoagulation and those with intraatrial thrombi, or those in whom rhythm control strategies have failed.¹⁵

The timing of attempted cardioversion is influenced by the duration of AT, the severity of the patient's symptoms, the adequacy of rate control, and the risk of thromboembolism. In stable patients with AT of a duration longer than 48 hours or of unknown duration, any mode of cardioversion (electrical, chemical, pacing, or ablation) should be delayed until the patient has been anticoagulated at appropriate levels for 3 to 4 weeks or transesophageal echocardiography (TEE) has excluded atrial thrombi. Even when the duration of AT is less than 48 hours, TEE also should be considered prior to cardioversion in patients with high thrombotic risk, including those with transposition of the great arteries, tetralogy of Fallot, Eisenmenger syndrome, Ebstein anomaly, intracardiac baffles, Fontan operation, mechanical valve prosthesis, prior thromboembolism, or severe ventricular dysfunction. Patients with Fontan palliation are at a particularly high risk for thromboembolic complications, such that TEE may be considered prior to cardioversion regardless of the anticoagulation status.

If urgency of cardioversion (because of severe symptoms or hemodynamic instability) precludes TEE, therapeutic doses of low-molecular-weight heparin or unfractionated heparin should be administered as soon as possible concurrent with, or preferably prior to, cardioversion.

Several options are available for termination of MRAT, including external direct-current cardioversion, antiarrhythmic drugs, and overdrive atrial pacing. Generally, direct-current cardioversion is preferred to chemical cardioversion given the higher efficacy and the lower risk of proarrhythmia, especially when the arrhythmia is poorly tolerated and prompt cardioversion is necessary. Intravenous ibutilide is a reasonable option for pharmacological cardioversion. Sotalol is less effective than ibutilide. Data are limited regarding the efficacy of other antiarrhythmic agents. Overdrive pacing is particularly useful in patients with preexisting atrial pacing wires in place (as part of a permanent pacemaker or defibrillator, or temporary epicardial pacing wires following cardiac surgery). For stable patients with adequate heart rate control and minimal symptoms, conversion to sinus rhythm may be deferred until catheter ablation, if this can be performed in a timely manner.¹⁷

Maintenance of Sinus Rhythm

Catheter Ablation

In adults with CHD and frequent recurrent symptomatic MRAT, catheter ablation is superior to antiarrhythmic drugs and is the preferred strategy in most patients. Referral to a center with expertise in adult CHD is strongly recommended. At experienced centers, catheter ablation carries short-term success rates of nearly 90%, but late recurrences of tachycardia, or development of new ones, are common. Nonetheless, ablation results are far superior to the extent of control obtained with medications alone.^{7,15,17}

Antiarrhythmic Drug Therapy

Chronic pharmacological therapy for MRAT in adults with CHD has limited long-term efficacy. Furthermore, most antiarrhythmic agents carry the risk of proarrhythmia, and many agents aggravate SND and compromise ventricular function, thus diminishing their utility in these patients, particularly in the absence of pacemaker therapy. Therefore long-term antiarrhythmic drug therapy is reserved for patients in whom catheter ablation is not feasible or is unsuccessful.¹⁷

Class IC agents (flecainide or propafenone) are an acceptable first-line therapy in patients with simple congenital defects and no other structural heart disease. However, those drugs should be avoided in patients with pathological hypertrophy of the systemic ventricle, systemic or subpulmonary ventricular dysfunction, or coronary artery disease. In those patients, both amiodarone and dofetilide may be considered. The use of sotalol is discouraged given the data linking it to increased mortality.¹⁷

Although amiodarone is likely the most effective antiarrhythmic agent for long-term rhythm control, its use should be reserved for patients in whom other antiarrhythmic agents have failed or are not tolerated. Even then, nonpharmacological options should be thoughtfully considered prior to committing a young patient to long-term amiodarone therapy, given the high risk of side effects.¹⁵ The drug may be used on a temporary basis to effect rhythm control for relief of symptoms prior to definitive ablation therapy (if this cannot be performed within a few days). However, amiodarone must be discontinued at least 1 to 2 weeks prior to the procedure to ensure that target tachycardias can be initiated and characterized for optimal ablation outcomes.

Surgical Ablation

Surgical ablation (RA maze procedure) may be considered in patients with AT refractory to medical therapy and catheter ablation, or in those requiring reoperation for hemodynamic reasons. This procedure is used most commonly for patients with failing Fontan procedures and the most refractory variety of MRAT and is usually combined with a revision of the Fontan connection or conversion from an older atriopulmonary anastomosis to a cavopulmonary connection. This typically includes debulking the RA, removing the thrombus, excising RA scar tissue, implanting an epicardial pacemaker, performing a modified RA maze procedure, and, in patients with prior documented AF, performing a left-sided maze procedure as well. Case series with short-term follow-up report promising results, with arrhythmia recurrence rates of 13% to 30%.

Pacemaker Implantation

Pacemaker implantation can be useful for those patients who have concomitant SND as a prominent component of their clinical picture. In these patients, prevention of severe sinus bradycardia not only allows for the use of drugs necessary for rate and rhythm control but also can potentially improve the hemodynamic status and often result in marked reduction in AT frequency. Pacemakers with advanced programming

features that incorporate AT detection and automatic burst pacing also can be beneficial in select cases, but they carry the risk of accelerating the atrial rate and must thus be used cautiously in patients with rapid AV conduction.

Prevention of Systemic Embolization

Long-term anticoagulation is recommended in patients with atrial arrhythmias and moderate or complex forms of CHD, regardless of the CHA₂DS₂-VASC score, since these patients exhibit a particularly high thrombotic risk. On the other hand, for patients with simple non-valvular forms of CHD, indications for long-term anticoagulation are similar to those in patients with AF (see Chapter 15).

New oral anticoagulants may be considered as an alternative to warfarin in patients with simple forms of CHD and no prosthetic heart valve or hemodynamically significant valve disease. On the other hand, the efficacy and safety of these agents have not been established to allow their utilization in patients with moderate or complex forms of CHD, especially those with Fontan surgery.¹⁵

Of note, clot formation in the RA is common in this patient population, especially in patients with old-style Fontan procedures, unlike patients without CHD in whom LA thrombus is the major concern.¹⁷

ELECTROCARDIOGRAPHIC FEATURES

As noted, MRATs in the adult population with CHD tend to have relatively slow atrial rates (in the range of 150 to 250 per minute) and can be associated with 1:1 AV conduction.

The surface electrocardiogram (ECG) morphology of RA free wall macroentry in a patient with a previous atriotomy is highly variable. The presence of complex anatomy secondary to congenital abnormalities, prior atrial surgery, or large low-voltage zones can modify atrial wavefront propagation in a nonuniform manner, with resulting altered atrial activation vectors or low-amplitude P waves.

P wave morphology on the surface ECG is usually of limited value for precise anatomical localization of macroreentrant circuits. Even typical AFL frequently manifests with an atypical 12-lead ECG appearance (so-called pseudo-atypical flutter) in the setting of markedly complex congenital malformation or surgical correction. Variation in the direction of wavefront rotation, the presence of coexisting conduction block in the atrium, and the presence of simultaneous typical AFL can add to the variability of P wave morphology. In addition, analysis of the flutter wave can be impeded by partial or complete concealment of the P wave within the QRS complexes or T waves when the AT is associated with 1:1 or 2:1 AV conduction (see Fig. 14.3).

The morphology of the atrial complex on the surface ECG can range from that similar to typical AFL to that characteristic of focal AT. Often, inverted flutter waves can be observed in lead V₁. Depending on the predominant direction of septal activation, RA free wall macroreentrant AT can mimic either clockwise or counterclockwise typical AFL.

MAPPING

Detailed knowledge of the patient's congenital and operative anatomy is essential for planning the ablation procedure, predicting the anatomical substrates for the tachycardia, interpreting the results of mapping techniques, and ascertaining how to access the systemic and pulmonary venous atria. Details of previous cardiac surgeries regarding surgical incisions, shunts, anastomoses, baffles, patches, or surgical ablation lesions need to be obtained from prior operative notes, hemodynamic catheterization reports, angiography, and other imaging studies. Preprocedural CMR or computed tomography (CT) can provide invaluable anatomical information on cardiac, vascular, and other intrathoracic

structures, and allow image integration with the electroanatomic map. Furthermore, intracardiac or transesophageal echocardiography can facilitate intracardiac catheter navigation and, when required, guide transseptal or transbaffle access.^{6,7}

Vascular and Cardiac Access

Feasibility and adequacy of vascular access must be confirmed in advance. Table 14.1 includes those conditions that are expected to pose vascular or cardiac chamber access challenges and methods that have been reported to allow catheter access. There is often limited opportunity to place the standard number of diagnostic electrode catheters due to access issues; alternative approaches to obtain endocardial access may include hepatic veins (via transhepatic puncture) and a retrograde approach to the atria from the ventricles.^{4,8,13}

Access to the Systemic Venous Atrium

The femoral veins may not provide access to the systemic venous atrium because of iliofemoral vein occlusion (resulting from multiple prior transvenous diagnostic and therapeutic cardiac procedures for the congenital anatomy) or interruption of the IVC. In these patients, access to the heart via the SVC (through the internal jugular and subclavian veins) or transhepatic venous access can be an alternative approach.^{6,7,18}

Access to the Arrhythmia Substrate and Cavotricuspid Isthmus

Knowledge of the location of the CTI (in the systemic versus pulmonary venous atrium), which is the most common target for catheter ablation, can help anticipate the need for transseptal/baffle access. Also, transseptal/baffle access can be required when non-CTI-dependent MRATs are mapped to the anatomical LA or to the portion of the native RA baffled to the pulmonary venous side of the circulation.

In patients with tetralogy of Fallot, atrial and ventricular septal defects, or anomalous pulmonary veins, postoperative cardiac anatomy approximates normal. In those patients, most MRAT circuits are located

in the RA, and cardiac access techniques, to a large extent, are similar to those in patients with MRAT and typical AFL in the absence of CHD. On the other hand, in patients who have undergone a Mustard or Senning procedure for D-transposition of the great arteries, postoperative anatomy of the atria presents unique challenges. The Mustard and Senning procedures direct the venous blood from the IVC, and IVC to the LV via the mitral valve, and the pulmonary venous blood to the RV via the tricuspid valve (“atrial switch procedure”). Thus the tricuspid valve is on the pulmonary venous side while the IVC is on the systemic venous side of the circulation; hence, the CTI is necessarily divided between the two sides (Fig. 14.4). Therefore access to the pulmonary venous atrium is almost always necessary for the ablation of MRAT including typical AFL, and can be accomplished via a retrograde aortic approach through the tricuspid valve or by transbaffle puncture.¹⁰

The most complex anatomy is confronted post Fontan procedures for univentricular hearts. Among patients who have had atriopulmonary (RA-to-pulmonary artery) anastomosis, ablation of the CTI requires access to the pulmonary venous atrium (via a fenestration in the baffle or a transbaffle puncture).¹³ Even in newer Fontan designs (total cavopulmonary connections), whereby the RA is bypassed to a large extent, using either a lateral tunnel or an extracardiac conduit, MRAT circuits are typically located on the pulmonary venous side of the tunnel or conduit, necessitating transbaffle access.^{1,12,14}

Access to the Coronary Sinus and Atrioventricular Node

It is important to recognize that the coronary sinus (CS) may not be easily accessible in patients with complex CHD. After a Mustard procedure for D-transposition of the great arteries, the location of the intraatrial baffle with respect to the CS and triangle of Koch is variable. The Mustard baffle can include or exclude the CS os, resulting in positioning the CS os in the pulmonary or systemic venous atrium, respectively (Fig. 14.5).^{4,7,8,11} During the Mustard and the Senning procedure, the intraatrial baffle is routinely sutured posterior to the AVN. As a result, the AVN is always located in the pulmonary venous atrium.¹⁰

TABLE 14.1 Conditions Associated With Challenges for Vascular and Cardiac Chamber Access

Occlusion or Access Challenge	Associated Conditions	Alternate Strategies

Fig. 14.4 Cavotricuspid Isthmus in D-transposition of the Great Arteries With Mustard and Senning Baffles. (A) Right anterior oblique view of a Mustard baffle is schematically depicted. (B) Axial view of a Senning baffle. Systemic venous return via the superior vena cava (SVC) and inferior vena cava (IVC) is directed toward the mitral valve (MV), whereas pulmonary venous return is directed toward the tricuspid valve (TV). Note that the cavotricuspid isthmus is divided in two, with the IVC portion on the systemic and TV portion on the pulmonary venous side of the circulation. CSO, Coronary sinus ostium; LPV, left pulmonary vein; RPV, right pulmonary vein. (From Khairy P, Van Hare GF. Catheter ablation in transposition of the great arteries with Mustard or Senning baffles. *Heart Rhythm*. 2009;6:283–289.)

Fig. 14.5 Triangle of Koch in D-transposition of the Great Arteries With Mustard Baffle. Three surgical variants for Mustard procedures are portrayed. (A) The coronary sinus is excluded from a baffle that is sutured posterior to its ostium (CSO), such that Koch's triangle is entirely in the pulmonary venous atrium. (B) The coronary sinus is surgically incised to redirect coronary venous flow into the Mustard baffle, with the Koch's triangle in the pulmonary venous atrium. (C) The anterior portion of the Mustard baffle is sutured anterior to the CSO to include coronary venous egress, such that the inferoposterior section of the Koch triangle is within the systemic venous atrium. AVN, Atrioventricular node; TV, tricuspid valve. (From Khairy P, Van Hare GF. Catheter ablation in transposition of the great arteries with Mustard or Senning baffles. *Heart Rhythm*. 2009;6:283–289, with permission.)

Access to the Pulmonary Venous Atrium

As noted, the arrhythmogenic substrate can be located partially or completely in the pulmonary venous atrium in patients with complex CHD, including those who have undergone a Mustard or Senning procedure for D-transposition of the great arteries, or a Fontan operation with an intraatrial baffle or extracardiac conduit. Ablating the tachycardia

substrate in these patients usually requires access to the pulmonary venous atrium.^{4,8,11}

Access to the pulmonary venous atrium can be technically challenging in patients with complex congenital defects and surgical baffles or septal patches. An understanding of the atrial septal anatomy, type of septal patches, extracardiac conduits, and any surgically created baffles,

Fig. 14.6 Angiography of a Senning Baffle. (A) Power contrast injection in the superior limb of the Senning baffle (SLB) shows unobstructed flow from the superior vena cava (SVC) with no intraatrial shunting. The reference catheter is positioned in the left atrial appendage (LAA), next to atrial pacing leads. (B) Power contrast injection of the inferior limb of the baffle (ILB) reveals a baffle leak, marked by the asterisks. This shunt was used to access the neo-left atrium (neo-LA). Flow into the neo-right atrium (neo-RA) is unimpeded. (C) Delayed imaging shows unobstructed pulmonary venous (PV) return into the neo-LA and toward the tricuspid valve (TV). MV, Mitral valve; RV, right ventricle. (From Khairy P, Van Hare GF. Catheter ablation in transposition of the great arteries with Mustard or Senning baffles. *Heart Rhythm*. 2009;6:283–289, with permission.)

as well the presence of baffle leaks or obstructions, is essential to plan access strategies to the pulmonary venous atrium. In addition, preprocedure CT or CMR or angiography of the systemic venous atrium during the procedure can help to investigate the presence of residual interatrial communications (e.g., baffle leak or septal patch defect), which might be used for transseptal access (Fig. 14.6). If a fenestration is not present, access to that chamber can require needle puncture of the native atrial septum, septal patch, or baffle. Although the retrograde aortic approach can provide access to the pulmonary venous atrium, it may not always permit adequate catheter reach or stability for successful ablation. These difficulties can be mitigated by using remote-controlled magnetic navigation (Stereotaxis; St. Louis, MO), which eliminates many of the limitations related to curve radius or reach.^{6,7,10}

Transseptal catheterization is feasible in most patients with prior surgical repair of an atrial septal defect. However, an understanding of the method of repair and utilization of intracardiac echocardiography (ICE) guidance are essential.¹⁹ In patients with a septal stitch or pericardial or Dacron patch, puncture can be achieved through the thickened septum or the patch. Transseptal access is typically not achievable through a Gore-Tex patch because of its resistant texture; instead, puncture can be performed directly through neighboring native interatrial tissue. When the patch is wide, sufficient free septal tissue for transseptal puncture may not be available, in which setting transseptal access to the LA may not be feasible. In patients with atrial septal defect closure devices, puncture is preferably performed at the portion of the septum located inferior and posterior to the closure device and not through the device itself. When areas of native septum are not available for transseptal access, recent reports described successful LA access through a direct puncture of the closure device.^{20,21} Radiofrequency (RF)-powered transseptal needles can facilitate access across the often thickened septum or synthetic baffles or patches.^{7,10}

Mapping Approach

Mapping may proceed using one of several strategies: if the patient presents during ongoing tachycardia, activation mapping can be used to characterize the arrhythmia's propagation, location of barriers and

potential isthmuses, and voltage. Alternatively, overdrive pacing may be used first, to determine tachycardia mechanism; although the vast majority of tachycardias in this population are due to macroreentry, an important minority are due to focal discharge for which linear ablation strategies (see below) have little benefit. Overdrive pacing may result in transient suppression followed by resurgence of these arrhythmias, rather than entrainment. If activation mapping is performed first, it may indicate a likely focal source with roughly centrifugal propagation, but this should not be taken as diagnostic of a focal process. Regardless of which strategy is used first (activation mapping or overdrive pacing), each should be performed if possible, since each provides important information regarding the tachycardia.

If the patient presents to the procedure in sinus rhythm, pacing can be performed at a number of sites from stationary catheters (CS, halo, etc.) for comparison of pure pacing activation sequences to those obtained while pacing from these sites during tachycardia that is subsequently initiated, in order to diagnose macroreentry. Voltage mapping can then be performed, determining low voltage or scar areas, likely atriotomy or baffle/patch regions, other barriers to propagation, such as valve annuli and caval orifices, and potential tachycardia isthmuses. The location of the normal conduction system and phrenic nerve can be determined, after which tachycardia can be initiated.

Exclusion of Cavotricuspid Isthmus Dependence

Exclusion of the CTI as part of the AT circuit is an important initial step because typical clockwise or counterclockwise AFL is the most common MRAT in patients with CHD (particularly in patients with simpler anatomical lesions such as the tetralogy of Fallot and atrial and ventricular septal defects), even if the P wave morphology is not characteristic for these arrhythmias. Exclusion of the CTI as part of the reentrant circuit can be established by any of the following: (1) demonstration of bidirectional activation of the CTI during AT, with resulting collision or fusion within the isthmus by activation from opposing directions (the low lateral RA and CS); (2) recording of double potentials separated by an isoelectric and constant interval throughout the full extent of the CTI during tachycardia; or (3) entrainment mapping from

the CTI demonstrating manifest atrial fusion with a long post-pacing interval.^{22,23}

If typical AFL is excluded, attention should be directed to potential reentrant circuits anchored by a right lateral atriotomy scar or a surgical patch. Subsequently, more complex or dual- or multiple-loop reentrant circuits (especially in patients with complex congenital malformations) should be considered; these require a more comprehensive and detailed mapping approach.

Identification of Barriers and Potential Lines of Block

Electroanatomic mapping (CARTO mapping system [Biosense Webster, Inc., Diamond Bar, CA, United States] or EnSite NavX system [St. Jude Medical, St. Paul, MN, United States]) is typically used to help facilitate identification of the macroreentrant circuit and the sequence of atrial activation during tachycardia and rapid visualization of the activation wavefront in the context of the relevant anatomy. These mapping systems allow for good reconstruction of 3-D anatomical shell of the often distorted cardiac chamber and integration of the created chamber geometry with preacquired cardiac CT or CMR images or with intra-procedural ICE or rotational angiography images (Fig. 14.7).¹

Mapping of MRATs in patients with CHD follows the same principles discussed for mapping of other types of MRATs (see Chapter 13 for detailed discussion). Initially, potential tachycardia circuit barriers are identified (during sinus rhythm or tachycardia) and marked on the electroanatomic map to help understand propagation of the reentrant

activation wavefront in relation to these barriers, identify potential slow-conducting pathways critical to the reentrant circuit, identify sites to target by entrainment mapping, and plan subsequent ablation strategy to abolish the tachycardia. The tricuspid annulus often provides one important barrier. Other naturally fixed barriers (i.e., independent of the precise form of activation and present also in sinus rhythm) include the IVC, SVC, and CS os. Acquired barriers include surgical incisions or patches, lines of block, and electrical scars. Confluent areas of low voltage (less than 0.05 mV) can localize areas of scar tissue. Such areas and surgically related scars, such as atriotomy scars in the lateral RA or atrial septal defect closure patches, are tagged as “scar” (see Figs. 14.1 and 14.2). Ensuring adequate catheter-tissue contact is essential, as low voltage due to lack of contact simulates scar. Fortunately, use of contact force-sensing catheters largely obviates this problem.

Identification of the Complete Reentrant Circuit

Electroanatomic activation mapping during AT is performed to define the atrial activation sequence and identify the complete reentrant circuit and its mid-diastolic critical isthmus. Reasonable numbers of points homogeneously distributed in the atrium must be recorded; it is important to record from all areas of the atrium (lateral RA can be difficult to reach and it can appear that the entire chamber has been sampled when, in fact, significant portions remain unmapped). The local activation time at each site is determined from the intracardiac bipolar electrogram and is measured in relation to the fixed intracardiac electric

Fig. 14.7 Atrial Macroreentry After the Mustard Procedure. (A) Anatomical reconstruction illustrating the anatomy of the pulmonary venous atrium (PVA) and systemic venous atrium (SVA) in a patient after the Mustard procedure. (B) An electroanatomic activation map of a macroreentry tachycardia in another patient with transposition of the great arteries corrected by the Mustard procedure. This map shows an activation map of the SVA from the left anterior oblique (LAO) view, with a reentry wavefront circulating around the mitral valve. AP, Anterior posterior; CS, coronary sinus; IVC, inferior vena cava; LAA, left atrial appendage; MV, mitral valve; PV, pulmonary vein; SVC, superior vena cava; TV, tricuspid valve. (From Houck CA, Teuwen CP, Bogers AJ, de Groot NM. Atrial tachyarrhythmias after atrial switch operation for transposition of the great arteries: treating old surgery with new catheters. *Heart Rhythm*. 2016;13:1731–1738, with permission.)

reference. Usually a catheter in the CS (if accessible) provides a stable reference electrogram. Using the onset of the local bipolar electrogram is preferable because it is easier to determine reproducibly when measuring heavily fractionated, low-amplitude atrial electrograms.

The complete reentrant circuit is the spatially shortest route of unidirectional activation encompassing the complete cycle length (CL) of the tachycardia in terms of activation timing and returning to the site of earliest activation. Using electroanatomic mapping, this translates into continuous progression of colors around the atrium, with close proximity of earliest and latest local activation. In addition, propagation of electrical activation superimposed on the 3-D anatomical reconstruction of the atrium can be visualized as a propagation map in relation to the anatomical and electrophysiological (EP) landmarks and barriers.

Unlike in mapping focal AT, in which tracking the site with the earliest presystolic local activation timing is the goal of mapping, there is no early or late region for MRAT because the wavefront is continuously propagating around the circuit. Entrainment pacing is performed at multiple atrial sites, especially around the tricuspid annulus and other atrial sites suspected to be critical to the reentry circuit, as identified by activation mapping. Entrainment mapping can be used to indicate the relation of pacing sites to the reentrant circuit (see Fig. 13.12). A (postpacing interval [PPI]–tachycardia cycle length [TCL]) difference of less than 50 milliseconds at the proximal CS distinguishes typical AFL from a lateral RA MRAT.²⁴

It is very important to remain vigilant during the mapping process and identify any change in the TCL or activation sequence, which can result from catheter manipulation, pacing maneuvers, or ablation. Such changes can indicate transformation of a multiple loop tachycardia by the interruption of one loop, a change in bystander activation, or a transition to another tachycardia, which requires reassessment. The transition may be obvious but is often quite subtle and sometimes imperceptible if only the CS activation is analyzed. Simultaneous recordings of RA activation (using a Halo catheter around the tricuspid annulus) and CS activation (using a decapolar catheter) can help rapid identification of tachycardia transformation; a change in tachycardia may be indicated by either a change in activation pattern (often subtle), a change in TCL, or both.

Sometimes, it can be impossible to map the entire circuit, especially in patients with complex CHD, because of the complex anomalies, suture lines, and baffles. In this setting, a combination of activation, entrainment, and voltage mapping data is used to identify the potential isthmus or zone of slow conduction critical to the reentrant circuit, which is then targeted by catheter ablation.

Identification of the Critical Isthmus

Once a scar or fixed barrier is localized, determining its role in supporting reentry is important in determining whether the isthmuses formed around it need ablation. Whether an isthmus is a critical part of the reentrant circuit can be determined by activation mapping during sustained stable reentry and entrainment mapping. The critical isthmus can lie between two anatomical barriers (e.g., the atriotomy scar and IVC orifice), or it can be a relatively narrow channel bounded by sites of scar or double potentials (marking anatomical or functional lines of conduction block). Electrograms recorded within the critical isthmus frequently exhibit wide, fractionated, low amplitude potentials (eFig. 14.1). The line of double potentials or fractionated, low-voltage electrograms also can often be recorded in NSR, to allow tentative localization of the scar and the associated anatomical isthmuses.

During electroanatomic activation mapping, when the onset of the window of interest is set at mid-diastole between two consecutive P waves, the mid-diastolic isthmus of the reentrant circuit can potentially be identified by the interface of early and late activation (i.e., the region

where “early meets late” on the color-coded activation map). High-density mapping is then performed in and around the isthmus to more precisely define its limits and width.

Once one or more potential isthmuses are identified during activation mapping and propagation mapping in relation to atrial scars, barriers, and lines of block, entrainment is performed to determine their role for supporting the reentrant circuit. Entrainment with concealed fusion should be sought; this indicates that the pacing site is in a protected isthmus located within or attached to the reentrant circuit. It should be recognized, however, that in patients with complex anatomy and surgical repairs, critical corridors of slow conduction can exist anywhere in the RA, and multiple circuits are the rule. As a consequence, entrainment with concealed fusion is highly nonspecific for most circuits in these patients. Therefore whether the protected isthmus is crucial to the reentrant circuit or just a bystander site needs to be verified by comparing the PPI with the TCL and the stimulus-exit interval with the electrogram-exit interval. Features of entrainment when pacing from different sites are listed in Table 13.2.^{22,23}

The critical isthmus of the reentry circuit often is an area of very slow conduction. As a result, stable overdrive pacing of the critical isthmus during MRAT can be difficult or impossible in these patients because of tachycardia interruption; in some cases, this occurs without propagation of the impulse and indicates that the pacing site is in a critical isthmus, despite being unable to show standard entrainment. Isthmus participation in the circuit is often proven by tachycardia interruption with catheter pressure (eFig. 14.2), as well as by tachycardia interruption and noninducibility after RF application in the area. Mechanical interruption of tachycardia can potentially render it non-inducible for extended periods of time thereafter; moving the catheter away from the site at which this occurred, the use of epinephrine, isoproterenol, or adenosine, or simply waiting up to 30 minutes may allow reinitiation of tachycardia. If the catheter tip electrode was being moved slowly and methodically when mechanical termination occurred, logging that site on the electroanatomic mapping system can facilitate subsequent ablation even if tachycardia cannot be reinitiated; however, if the catheter movements around the time of mechanical interruption were more coarse, caution should be exercised in determining what site may have been affected by the catheter trauma.

In some cases, the best ablation target is a systolic, rather than diastolic, electrogram; this occurs especially in very large and scarred atria, where very slow propagation occurs from a reentrant corridor to the rest of the atrium. Such sites are uninteresting from an activation mapping perspective and only can be discovered by overdrive pacing at sites that have very delayed conduction during sinus rhythm, or are in regions that are suspected to contain a diastolic corridor from voltage or activation mapping during other tachycardias. Such overdrive pacing at these sites produces a perfect intracardiac pace match with tachycardia, with a very long stimulus-P interval and PPI approximating TCL.

ABLATION

Target of Ablation

The choice of ablation sites should be among those segments of the reentry circuit that offer the most convenient and safest opportunity for creating a conduction block. Among other factors are the isthmus size, the anticipated catheter stability, and the risk of damage to adjacent structures (e.g., phrenic nerve, sinus node, and AVN).

Ablation is performed by targeting the narrowest identifiable isthmus of conduction accessible within the circuit (allowing the best electrode-tissue contact along the desired line). The ablation line is chosen to transect an area critical for the circuit and, at the same time, connect two anatomical areas of block, an electrically silent area to an anatomical

eFig. 14.1 Postatriotomy Right Atrial Macroreentry. Electrocardiogram leads and intracardiac recordings are shown during non-isthmus-dependent macroreentrant atrial tachycardia (AT) in a patient with a repaired atrial septal defect. A prolonged, fractionated diastolic electrogram is observed at the ablation site. Note the repetitive recording (*arrow*) that nearly spans the cardiac cycle. The patient had a right atriotomy as the basis of atrial tachycardia and incurred complete heart block during surgery (hence the ventricular pacemaker). Abl_{dist}, Distal ablation site; CS_{dist}, distal coronary sinus; CS_{mid}, middle coronary sinus; CS_{prox}, proximal coronary sinus; His_{prox}, proximal His bundle; TA_{dist}, distal tricuspid annulus; TA_{prox}, proximal tricuspid annulus.

eFig. 14.2 Catheter-induced Termination of Macroreentrant Atrial Tachycardia (AT). Electrocardiogram leads and intracardiac recordings are shown during an episode of non-isthmus-dependent atrial macroreentrant AT in a patient with prior atriotomy. The episode had lasted 3 months at the time of the study, yet catheter pressure at the site from which the distal ablation site (*Abl_{dist}*) recording was made terminated AT twice. Note the multicompartment electrogram (*blue arrow*), the last portion of which is missing when AT terminates (*red arrow*). *Abl_{prox}*, Proximal ablation site; *CS_{dist}*, distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *His_{dist}*, distal His bundle; *His_{prox}*, proximal His bundle; *TA_{dist}*, distal tricuspid annulus; *TA_{prox}*, proximal tricuspid annulus.

zone of block (e.g., IVC, SVC, or tricuspid annulus), or two electrically silent areas.

Although successful ablation is most frequently achieved by targeting the “slow zone” of atrial conduction presumed necessary for maintenance of reentry, some investigators have emphasized the need for considering both the anatomy and EP simultaneously to identify a susceptible bridge of tissue, which connects two areas of electrical block (see Fig. 13.13). Such an approach requires careful review of the details of the atrial surgery, in addition to detailed mapping of the atria in its “usual” rhythm (i.e., sinus or atrial pacing) and during reentry.

Because typical AFL is the most common mechanism underlying MRAT in the patient population with CHD, determination of the role of the CTI in supporting reentry is evaluated first, and the CTI should be targeted by ablation if it is proved to be critical to the AT circuit (Fig. 14.8). Ablation of the CTI may also be reasonable in all CHD patients with MRAT, even those presenting with non-CTI-dependent RA macroreentry, because the CTI can support reentry in most patients with prior right atriotomy. Importantly, in some congenital heart malformations (e.g., AV canal defects), the AVN and His bundle can have unusual locations, and can be displaced just anterior to the ostium of the CS. Consequently, ablating in the right inferior paraseptal region can cause AV block. Therefore for patients with CTI-dependent macroreentry, the location of the conduction system should be carefully characterized and more lateral ablation lines are generally preferred, to prevent AV block.

If participation of the CTI in the reentrant circuit is excluded, or if the tachycardia persists or transforms into a different tachycardia after ablation of the CTI, participation of the lateral RA wall in the AT circuit should be assessed. Non-CTI-dependent RA macroreentry is frequently localized to the free wall of the RA, anchored by the atriotomy scar, in which setting the ablation strategy includes any of the following: (1) to target the slow conduction area (critical isthmus of the reentrant circuit) as identified by detailed activation and entrainment mapping (see Fig. 14.2); (2) to extend the atriotomy (double potential or scar) to the IVC (see Fig. 14.1); or (3) to extend the scar area to the SVC (see

Fig. 14.1). The last approach can result in injury of the sinus node or phrenic nerve. Therefore, when possible, extending the atriotomy to the IVC is preferable (and is generally technically easier). As noted, additional ablation of the CTI may be considered in these patients because these circuits are often combined with a circuit around the tricuspid annulus in a figure-of-8 reentry, such that ablation of both the CTI and one of the lateral wall options must be performed to eliminate and prevent reentrant AT (see Fig. 14.8).

Rarely, more complex circuits, such as around the right septal patch, as seen in patients with Mustard or Senning repairs, are observed. However, the approach to ablation is the same: the area with slow conduction or scar is extended to an anatomical obstacle.

Another focus for reentry circuits is the region of the sinus node. These circuits may be quite small, often manifesting as focal tachycardia in the sinus node region, and they can often be ablated in a single location without establishing a particular line of block.

In patients with incomplete maps, a combination of activation, entrainment, and voltage mapping data is used to identify the potential isthmus or zone of slow conduction critical to the reentrant circuit, which is then targeted by catheter ablation. When limitations to this approach still exist (from poor inducibility or frequent change in morphology of the tachycardia), a stepwise ablation strategy may be employed. Because the reentrant circuit in most patients is anchored to the CTI or the atriotomy scar, ablation of the CTI is initially performed. Then, if the tachycardia persists, linear ablation is carried out by targeting the isthmuses related to the lateral atriotomy scar (i.e., connecting the atriotomy to either the IVC or SVC). Additional ablation lines connecting other areas of conduction block (scar, surgical incision, septal patch, baffle, or natural barriers) may be considered based on substrate mapping findings.

Ablation Technique

Once the ablation target is identified, ablation involves placing a series of RF lesions to sever the critical isthmus and connect two anatomical or surgical barriers. Because some congenital malformations and

Fig. 14.8 Dual Right Atrial (RA) Macroreentry Circuits. (A) Right posterolateral view of electroanatomic (CARTO) activation map of incisional macroreentrant RA tachycardia. (B) Right anterolateral view of electroanatomic (CARTO) activation map of typical atrial flutter in the same patient. Linear radiofrequency ablation (red dots) is performed to sever the isthmus between the atriotomy scar and the inferior vena cava (IVC) as well as linear ablation across the cavotricuspid isthmus. Ablation is facilitated by correlating activation mapping findings with those of voltage mapping. SVC, Superior vena cava; TA, tricuspid annulus.

surgical repairs are associated with myocardial hypertrophy and extensive fibrotic regions, creation of confluent and transmural lesions can be difficult, especially in the presence of low intracavitary blood flow that often impairs convective cooling and limits RF energy. Therefore irrigated (25 to 50 W) or 8-mm (target temperature, 60°C to 70°C; 50 to 60 W) tip RF catheter is usually necessary. RF application is maintained for up to 60 seconds until the bipolar atrial potential recorded from the ablation electrode is decreased by 80% or split into double potentials, indicating local conduction block. The coalescence of multiple RF lesions can be facilitated by the use of an electroanatomic mapping system.

In view of the often dilated and distorted atrial chambers, the use of long, preformed or deflectable vascular sheaths is helpful to augment the reach of the ablation catheter and ensure adequate and stable catheter-tissue contact. ICE and contact-force catheter contact technology can be used to ensure good contact.^{1,11}

During delivery of RF energy, the tachycardia can terminate, or its CL can increase transiently or permanently. These findings usually indicate that the lesions have affected the circuit and should prompt continuation of RF delivery or extension of the lesion to ensure the achievement of complete conduction block across the isthmus. Alternatively, the tachycardia can transform to a different loop or to a different tachycardia (rather than terminate), as indicated by a change in activation sequence or CL, or both, in which setting the reassessment of the new tachycardia mechanism and location is necessary before continued RF ablation. Importantly, persistence of the tachycardia with little discernible change in CL or activation sequence despite extensive ablation across an isthmus, which was initially found to be critical to the tachycardia circuit (by entrainment mapping techniques), usually indicates multiple circuits, often with a double-loop type of reentry. In this setting, it is imperative to verify whether the isthmus is still critical to the reentrant circuit by repeating the entrainment mapping. Sometimes, complete isthmus block is already achieved (as suggested by the presence of double potentials along the ablation line), and the isthmus is no longer participating in the tachycardia circuit (as suggested by entrainment mapping findings), as a result of a change in the tachycardia circuit that occurred during ablation. This can be observed during ablation of the CTI in the setting of double-loop reentry that uses the lateral wall as well as the CTI. Achieving complete block across the CTI does not eliminate the tachycardia that is now dependent on a different isthmus (e.g., the lateral RA around or within the atriotomy scar).

Ablation near the region of the superior crista terminalis and SVC can result in right phrenic nerve injury and diaphragmatic paralysis. Pacing with a high output (10 mA at 2 milliseconds) from the ablation catheter at the target site can help identify the location of the right phrenic nerve. In addition, suspicion of phrenic nerve injury should be considered in the case of hiccup, cough, or decrease in diaphragmatic excursion during energy delivery. Early recognition of phrenic nerve injury during RF delivery allows the immediate interruption of the application prior to the onset of permanent injury and is associated with the rapid recovery of phrenic nerve function. A good practice is to delineate the course of the phrenic nerve during the baseline rhythm by pacing at high current strength and logging the sites of phrenic capture (as indicated by diaphragmatic contraction) on the electroanatomic mapping system. Ablation in these areas should be avoided if possible. In some cases, the phrenic nerve can have major branches; therefore simply avoiding ablation at sites of known phrenic capture may be insufficient to avoid damage to a portion of the nerve, and one should consider high output pacing at candidate ablation sites prior to ablation. This of course risks termination or transformation of tachycardia so should be used with care.

Endpoints of Ablation

Tachycardia Termination

Sudden termination of AT during RF application suggests that the lesion has affected a critical isthmus, and that site should be targeted for additional lesions. However, AT termination during RF application is not adequate as the sole criterion of a successful ablation because such an AT can also terminate spontaneously, secondary to premature atrial complexes induced by RF energy delivery, and by partial, rather than complete, isthmus block.

Noninducibility of Tachycardia

To use this criterion as a reliable endpoint, careful assessment of inducibility should be performed prior to ablation, and the feasibility and best method of reproducible induction of the AT should be documented at baseline before ablation. In the setting of easy inducibility prior to ablation, one can consider the lack of inducibility as an indicator of successful ablation. Noninducibility of the arrhythmia is inapplicable if the original arrhythmia is incessant, noninducible at baseline, or was inadvertently terminated mechanically. Noninducibility may also reflect conduction delay in the critical isthmus, and not stable block, or it may be secondary to changes in autonomic tone.

Documentation of a Line of Block

Complete stable conduction block within the reentry path is the most useful and objective endpoint. For a vertically oriented RA free wall atriotomy, assessment of conduction block can be facilitated by the use of a multielectrode Halo catheter. Several techniques can be used to confirm complete conduction block across the ablation line:

Double potentials. The mapping catheter is used to retrace the ablation line during atrial pacing from either side of the ablation line. The demonstration of a continuous corridor of widely split double potentials recorded along the entire length of the ablation line confirms the presence of block. When there is a gap in a line of block, the isoelectric interval between the double potentials shortens the closer the electrograms are to the gap. At the gap, in the line of block, double potentials are no longer present, and the electrogram is typically long and fractionated, but also can be discrete.

Atrial activation sequence. Pacing close to the ablation line and demonstration of marked delay and reversal in the direction of activation on the opposite side of the ablation line is consistent with conduction block across the ablation line, although very slow conduction can be difficult to exclude. Electroanatomic activation mapping during pacing demonstrates the earliest activation at the side of the ablation line ipsilateral to the pacing site, while the latest activation occurs at the contralateral side, and an early-meets-late zone along the entire length of the ablation line. In the setting of incisional RA macroreentry treated with linear ablation connecting the scar to the IVC, the presence of conduction block across the ablation line can be confirmed by demonstrating a high-to-low activation of the RA on one side of the ablation line during pacing at the low RA on the contralateral side of the ablation line.⁶

Differential pacing. Atrial pacing is performed at two separate sites on the same side of the ablation line: one site is very close to the ablation line and the second site is 10 to 20 mm further away. Local activation time is recorded on the contralateral side of the ablation line. In the presence of conduction block across the ablation line, moving the pacing site away from the ablation line shortens the conduction time to the contralateral side, and shortens the distance between the double potentials straddling the ablation line. Withdrawal of the pacing site further away from the ablation line results in a delay of the first component of the double potentials (which represents activation on

the side of the ablation line ipsilateral to the pacing site). In contrast, the second component of the double potentials (which represent activation on the contralateral side of the ablation line) becomes activated earlier since the length of the detour the wavefront has to travel around the line of block is shortened by the new site of pacing. As a consequence, the separation of double potentials decreases. On the other hand, in the setting of incomplete block, both components of the double potentials are the result of sequential activation by the same paced wavefront propagating across the ablation line. Therefore withdrawal of the pacing site further away from the ablation line causes a similar degree of delay of the timing of both components of the electrogram (relative to the pacing stimulus), so that the interval between the double potentials remains constant.

Outcome

Acute and long-term success rates of catheter ablation of MRATs in CHD patients are influenced by the complexity of underlying congenital defect and surgical repair, and the complexity of the reentry circuits. In addition, atrial enlargement and myocardial hypertrophy and extensive scarring in this patient population can interfere with RF energy delivery, and limit RF lesion depth. Nevertheless, the combined use of 3-D mapping and irrigated ablation has improved the acute procedural success rate to the range of 66% to 97% in experienced centers. However, recurrence rates after acutely successful catheter ablation still remain relatively high (10% to 59%), particularly in the Fontan group. These can be the same tachycardias or new tachycardias, as the substrate continues to change with time. Nonetheless, the overall results are far superior to pharmacological therapy.^{1,7,11}

Surgical Left Atrial Appendage Exclusion, 540**PATHOPHYSIOLOGY****Classification of Atrial Fibrillation**

Atrial fibrillation (AF) has been described as lone, idiopathic, nonvalvular, valvular, paroxysmal, persistent, or permanent. Each of these classifications has implications regarding mechanisms as well as response to therapy. At the initial detection of AF, it is impossible to know the subsequent pattern of duration and frequency of recurrences. Thus a designation of first-detected episode of AF is made on the initial diagnosis, irrespective of the duration of the arrhythmia. When the patient has experienced two or more episodes, AF is classified as recurrent.

After termination of an episode of AF, the rhythm can be classified as paroxysmal or persistent (Table 15.1). *Paroxysmal AF* is characterized by self-terminating episodes that generally last less than 7 days. *Persistent AF* lasts longer than 7 days and often requires electrical or pharmacological cardioversion. Subcategories of persistent AF (according to arrhythmia duration) include *early persistent AF* (defined as AF that is sustained beyond 7 days but is less than 3 months in duration) and *longstanding persistent AF* (defined as AF that is sustained longer than 1 year but is being considered for ablation). *Permanent AF* refers to AF in which cardioversion has failed or AF that has been sustained for more than 1 year and further attempts to restore normal sinus rhythm (NSR) were unsuccessful or have been abandoned.¹

Although useful, this arbitrary classification does not account for all presentations of AF and overlap occurs. Paroxysmal AF often progresses to longer, non-self-terminating episodes. In addition, the pattern of AF can change in response to treatment. AF that has been persistent can become paroxysmal with antiarrhythmic drug therapy, and AF that had been permanent can potentially be cured or made paroxysmal by surgical or catheter-based ablation. Furthermore, the distinction between

TABLE 15.1 Classifications of Atrial Fibrillation

AF Pattern	Definition
First diagnosed AF	AF that has not been diagnosed before, irrespective of the duration of the arrhythmia or the presence and severity of AF-related symptoms.
Paroxysmal AF	Self-terminating, in most cases within 48 hours. Some AF paroxysms may continue for up to 7 days. ^a
Persistent AF	AF that lasts longer than 7 days, including episodes that are terminated by cardioversion, either with drugs or by direct current cardioversion, after 7 days or more.
Longstanding persistent AF	Continuous AF lasting for ≥1 year when it is decided to adopt a rhythm control strategy.
Permanent AF	AF that is accepted by the patient (and physician). Hence, rhythm control interventions are, by definition, not pursued in patients with permanent AF. Should a rhythm control strategy be adopted, the arrhythmia would be re-classified as “longstanding persistent AF.”

^aThe distinction between paroxysmal and persistent AF is often not made correctly without access to long-term monitoring. Hence, this classification alone is often insufficient to select specific therapies. If both persistent and paroxysmal episode are present, the predominant pattern should guide the classification.

AF, Atrial fibrillation.

From Kirchhof P, Benussi S, Kotecha D, et al. 2016 ESC guidelines for the management of atrial fibrillation developed in collaboration with EACTS. *Eur Heart J*. 2016;37:2893–2962.

Fig. 15.1 The Pathophysiological Triangle in Atrial Fibrillation (AF). (From Kottkamp H, Schreiber D. The substrate in “early persistent” atrial fibrillation. *JACC Clin Electrophysiol.* 2016;2:140–142.)

persistent and permanent AF is not only a function of the underlying arrhythmia but also a reflection of the clinical pragmatism of the patient and physician. The severity of symptoms associated with AF, anticoagulation status, and patient preference all affect the decision of whether and when cardioversion will be attempted. This decision would then affect the duration of sustained AF and could lead to a diagnosis of persistent or permanent AF. Furthermore, significant discrepancies exist between the clinical AF classification and the objective cardiac device-derived assessments of AF temporal persistence (in AF patients with pacemakers or defibrillators) (eFig. 15.1). Patients within the same clinical class (“paroxysmal” or “persistent” AF) are highly heterogeneous with regard to AF temporal persistence, arrhythmia burden, and stages of disease.²

AF can be classified as valvular or nonvalvular. The 2012 focused update of the European Society of Cardiology (ESC) guidelines defined valvular AF as rheumatic valvular disease (predominantly mitral stenosis) or prosthetic heart valves. Similarly, the 2014 American Heart Association/American College of Cardiology/Heart Rhythm Society (AHA/ACC/HRS) guidelines for the management of patients with AF defined nonvalvular AF as AF in the absence of rheumatic mitral stenosis or a mechanical heart valve, but explicitly added bioprosthetic heart valves or mitral valve repair within the “valvular heart disease” group.^{3,4}

The terms “lone” and “idiopathic” AF have been variably defined in the literature, but they generally refer to younger AF patients who have no clinical or echocardiographic evidence of cardiopulmonary disease, hypertension, or diabetes mellitus. However, this categorization is being abandoned since the category of lone AF no longer has mechanistic or clinical utility. Similarly, the term “chronic AF” has variable definitions and should not be used to describe populations of patients with AF.^{5,4}

Mechanism of Atrial Fibrillation

The pathogenesis of AF remains incompletely understood and is believed to be complex, multifactorial, and variable in different individuals. Two concepts of the underlying mechanism of AF have received considerable attention: factors that trigger AF and factors that perpetuate the arrhythmia. In general, patients with frequent, self-terminating episodes of AF are likely to have a predominance of factors that trigger AF, whereas patients with AF that does not terminate spontaneously are more likely to have a predominance of perpetuating factors. Although such gross generalization has clinical usefulness, often there is considerable overlap

of these mechanisms. The typical patient with paroxysmal AF has identifiable ectopic foci initiating the arrhythmia, but these triggers cannot be recorded in all patients. Conversely, occasional patients with persistent or permanent AF can be cured of their arrhythmia by ablation of a single triggering focus, a finding suggesting that perpetual firing of the focus can potentially be the mechanism sustaining this arrhythmia in some cases.^{6,7}

Advanced mapping technologies, along with studies in animal models, have suggested the potential for complex pathophysiological substrates and modifiers responsible for AF (Fig. 15.1), including the following: (1) continuous aging or degeneration of atrial tissue and the cardiac conduction system; (2) progression of structural heart disease (e.g., valvular heart disease and cardiomyopathy); (3) myocardial ischemia, local hypoxia, electrolyte derangement, and metabolic disorders (e.g., atherosclerotic heart disease, chronic lung disease, hypokalemia, and hyperthyroidism); (4) inflammation related to pericarditis or myocarditis, with or without cardiac surgery; (5) genetic predisposition; (6) drugs; and (7) autonomic influences.^{1,8}

Mechanism of Initiation of Atrial Fibrillation

The factors responsible for the onset of AF include triggers that induce the arrhythmia and a receptive substrate that sustains it. The triggers are diverse yet may not cause AF in the absence of other contributors. There are two different types of arrhythmias that can potentially play a role in generating AF: premature atrial complexes (PACs) that initiate AF (focal triggers) and focal tachycardia that either induces fibrillation in the atria or mimics AF by creating a pattern of rapid and irregular depolarization wavefronts in the atria for as long as the focus continues to discharge.⁹

The mechanism of initiation of AF is not certain in most cases and likely is multifactorial. Triggers propagating into the atrial myocardium can potentially initiate multiple reentrant wavelets and AF. In some patients with paroxysmal AF, impulses initiated by ectopic focal activity propagate into the left atrium (LA) and encounter heterogeneously recovered tissue. If reentry were assumed to be the mechanism of AF, initiation would require an area of conduction block and a wavelength of activation short enough to allow the reentrant circuits to persist in the myocardium.

Once triggered, AF can be self-sustained, in which case the continued firing of the focus may not be required for maintenance of the arrhythmia, and ablation of the focus may not terminate AF, but can potentially

eFig. 15.1 Clinical Versus Cardiac Device-Derived Classification of Atrial Fibrillation (AF). (A) Distribution of the AF burden in the clinical classification groups (paroxysmal, persistent). (B) The probability of being in either of the clinical classification groups at any given AF burden level (conditional density plot). For example, at an AF burden of 0.2, the probability of being classified as “paroxysmal” or “persistent” was approximately 0.8 and 0.2, respectively. As the AF burden increases, intuitively one would expect that the probability of being classified as “paroxysmal” AF decreases and the probability of being classified as “persistent” increases. Unexpectedly, at AF burdens of 0.9, the probability of being classified as “paroxysmal” or “persistent” was also approximately 0.8 and 0.2, respectively, showing the disconnection between clinical classification and temporal persistence. Even at very high burdens the vast majority of patients were classified as having “paroxysmal” AF. (C) Distribution of the atrial fibrillation (AF) burden in the device-derived classification groups (no AF, paroxysmal, persistent, permanent). (D) The probability of being in any of the device classification groups at any given AF burden level (conditional density plot). As AF burden increases, the probability of being classified in a progressively more severe classification (no AF, paroxysmal, persistent, permanent) increases. This is in contrast to the clinical AF classification (B). (From Charitos EI, Pürerfellner H, Glotzer TV, et al. Clinical classifications of atrial fibrillation poorly reflect its temporal persistence: insights from 1,195 patients continuously monitored with implantable devices. *J Am Coll Cardiol.* 2014;63:2840–2848.)

prevent the reinitiation of AF. Conversely, initiation and maintenance of AF can depend on uninterrupted periodic activity of a few discrete reentrant or triggered sources localized to the LA (i.e., focal drivers), emanating from such sources to propagate through both atria and interact with anatomic or functional obstacles, thus leading to fragmentation and multiple wavelet formation. Factors such as wavefront curvature, sink-source relationships, and spatial and temporal organization all are relevant to the understanding of the initiation of AF by the interaction of the propagating wavefronts with such anatomic or functional obstacles. Indeed, all these factors, which differ from triggers, importantly affect the initiators of AF.

AF triggering factors include sympathetic or parasympathetic stimulation, bradycardia, PACs (which may be the most common cause; Fig. 15.2), atrial flutter (AFL; see Fig. 12.2), supraventricular tachycardias (SVTs; especially those mediated by atrioventricular [AV] bypass tracts [BTs]; Fig. 15.3), and acute atrial stretch. Identification of these triggers has clinical importance because treatment approaches directed at elimination of the triggers (e.g., catheter ablation of the initiating PACs or SVT) can be curative in selected patients.

PV triggers. Triggering foci of rapidly firing cells within the sleeves of atrial myocytes extending into the pulmonary veins (PVs) have been shown to be the underlying mechanism in most cases of paroxysmal AF. Supporting this idea are clinical studies of impulses generated by single foci propagating from individual PVs or other atrial regions to

the remainder of the atria as fibrillatory waves and abolition of AF by radiofrequency (RF) ablation to eliminate or isolate the PV foci. The PVs also represent the main trigger site for AF initiation in patients with recurrent persistent AF, with an overall prevalence similar to that found in patients with paroxysmal AF.¹⁰

Based on several features, the thoracic veins are highly arrhythmogenic. The PV-LA junction has discontinuous myocardial fibers separated by fibrotic tissues and hence is highly anisotropic. Insulated muscle fibers can promote reentrant excitation, automaticity, and triggered activity. These regions likely resemble the juxtaposed islets of atrial myocardium and vascular smooth muscle in the coronary sinus (CS) and AV valves that, under normal circumstances, manifest synchronous electrical activity but develop delayed after-depolarizations and triggered activity in response to catecholamine stimulation, rapid atrial pacing, or acute stretch.

Furthermore, the PVs of patients with paroxysmal AF demonstrate abnormal properties of conduction so that there can be markedly reduced refractoriness within the PVs, progressive conduction delay within the PV in response to rapid pacing or programmed stimulation, and often conduction block between the PV and the LA. Such findings are much more common in patients with paroxysmal AF than in normal subjects. Rapidly firing foci can often be recorded within the PVs with conduction block to the LA. Administration of catecholamines such as isoproterenol can lead to shortening of the LA refractory period, thereby

Fig. 15.2 Atrial Fibrillation (AF) Induction by Premature Atrial Complexes (PACs) Originating From the Right Superior Pulmonary Vein (PV). Two monomorphic PACs (arrows) occur at short coupling intervals and are inscribed within the T wave. The second PAC (red arrows) triggers AF.

Fig. 15.3 Atrial Fibrillation (AF) Induction by Orthodromic Atrioventricular Reentrant Tachycardia (AVRT). *CS_{dist}*, Distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *HRA*, high right atrium; *RVA*, right ventricular apex.

allowing these foci to propagate to the LA and induce AF. These discontinuous properties of conduction within the PV can also provide a substrate for reentry within the PV itself, although this remains to be proven.

Non-PV triggers. Although more than 90% of AF triggering foci that are mapped during electrophysiological (EP) studies in patients with paroxysmal AF occur in the PVs, foci within the superior vena cava (SVC), small muscle bundles in the ligament of Marshall, and the musculature of the CS have been identified. Although these latter locations of triggering foci are uncommon in patients with paroxysmal AF, the common factor is that the site of origin is often within a venous structure that connects to the atrium. Other sites of initiating foci can be recorded in the LA wall or along the crista terminalis in the right atrium (RA).

Mechanism of Maintenance of Atrial Fibrillation

Having been initiated, AF can be brief; however, various factors can act as perpetuators, thus ensuring the maintenance of AF. One factor is the persistence of the triggers and initiators that induced the AF, which then act as an engine driving the continuation of AF. In this setting, maintenance of AF is dependent on the continued firing of the focus (the so-called “focal driver”). Alternatively, AF can persist even in the absence of the focal drivers. Without focal drivers, persistence of AF results from a combination of electrical and structural remodeling processes characterized by atrial dilation and shortening of atrial refractoriness (see later). These factors can be present at baseline but can also be induced by the AF itself.

The mechanisms responsible human AF remain controversial. Several theories have been proposed to explain the EP mechanisms underlying AF, including the multiple wavelet theory and the localized source hypothesis.¹¹

Multiple wave reentry hypothesis. For many years, the “multiple wave reentry” hypothesis was the most widely held theory on the maintenance of AF, and was a key development in our understanding of the

mechanism of AF. On the basis of a computer model of AF, Moe and associates hypothesized that AF is sustained by multiple randomly wandering wavelets in both atria that collide with each other and extinguish themselves or create new, daughter wavelets that continually reexcite the atria and perpetuate the arrhythmia.¹² Those functional reentrant circuits are therefore unstable; some disappear, whereas others reform. These circuits have variable, but short, cycle lengths (CLs) to which atrial tissue cannot respond in a 1:1 fashion. As a result, functional block, slow conduction, and multiple wavefronts develop. It has been suggested that at least four to six independent wavelets are required to maintain AF. These wavelets rarely reenter themselves but can reexcite portions of the myocardium recently activated by another wavefront, a process called random reentry. In simulated cardiac tissue, multiple wavelet fibrillation is equivalent to spiral/scroll waves that are inherently unstable and spontaneously develop wavebreaks along the arm of the rotor which then form daughter wavelets.¹¹ Because multiple wave reentry fibrillation is purely reentrant, its initiation requires a trigger to create the original unstable spiral/scroll wave that subsequently breaks up to create daughter wavelets; however, once initiated, additional triggers are no longer required to maintain fibrillation.¹¹

The persistence of multiple-circuit reentry depends on the ability of a tissue to maintain enough simultaneously reentering wavefronts so that electrical activity is unlikely to extinguish simultaneously in all parts of the atria. Therefore the larger the number of wavelets present, the more likely the arrhythmia will be sustained. The number of wavelets coexisting at any moment depends on the atrial mass, excitation wavelength, refractory period, conduction velocity, and anatomic obstacles in different portions of the atria. In essence, a large atrial mass with short refractory periods and prominent conduction delay would yield increased wavelets and would present the most favorable situation for AF to be sustained.

Clinical support for this hypothesis seemed to come from the surgical maze and some substrate-based catheter ablation procedures, which were proposed to result in dividing the atrial into small electrical

compartments and, thus, disallowing maintenance of the randomly propagating wavelets.¹³ The reentrant circuits that comprise multiple wave reentry are functional, multiple, and dynamic; thus ablation of multiple wave reentry is not aimed at eliminating the possibility of its existence but at maximizing the probability of its spontaneous termination through collisions between circuit cores and unexcitable tissue boundaries via atrial debulking and compartmentalization.¹⁴

Localized source hypothesis. In contrast to the nonhierarchical, self-sustaining disorganized electrical activity implicated in the multiple wavelet theory, recent evidence suggests the presence of hierarchical electrical organization in which localized sources drive disorganized activity. This hypothesis suggests that AF is intermittently maintained by a small number of localized (spatially stable) high-frequency sources with periods of self-sustaining disorganization. Rotors and focal sources exhibit 1:1 activation within their spatial domain, with peripheral disorganization. This concept was supported by experimental studies using high-resolution optical mapping, which demonstrated spatial and temporal organization during AF. Localized sources can be either discrete foci with centrifugal spread of activation or small anatomic reentry circuits or functional rotors.¹³

When cardiac impulses are continuously generated at a rapid rate from any source or any mechanism, they activate the tissue of that cardiac chamber in a 1:1 manner, up to a critical rate. Once this critical rate is exceeded, not all the tissue of that cardiac chamber can respond in a 1:1 fashion (e.g., because the CL of the driver is shorter than the refractory periods of those tissues), and “fibrillatory conduction” develops. Fibrillatory conduction can be caused by spatially varying refractory periods or by the structural properties of atrial tissue, with source-sink mismatches providing spatial gradients in the response. Fibrillatory conduction is characterized by activation of tissues at variable CLs, all longer than the CL of the driver, because of variable conduction block; in that manner, activation is fragmented. This is the mechanism of AF in several animal models in which the driver consists of a stable, abnormal automatic focus of a very short CL, a stable reentrant circuit with a very short CL, or an unstable reentrant circuit with a very short CL. It also appears to be the mechanism of AF in patients in whom activation of the atria at very short CLs originates in one or more PVs. The impulses from the PVs seem to precipitate and maintain AF.¹³

The concept of fibrillatory conduction is relevant to the “mother rotor fibrillation” hypothesis, in which a fast stationary or meandering spiral/scroll wave in one region of the tissue develops peripheral wavebreaks as the spiral/scroll arm propagates into surrounding tissue with longer refractory periods. Though some investigators suggest that these mother rotors are likely fixed, others have suggested that they may precess (i.e., wobble), albeit in small fairly well-defined areas. In atria with extensive fibrosis, multiple stable rotors can possibly coexist in different regions, insulated by intervening tissue that cannot maintain 1:1 conduction. This variant is equivalent to mother rotor fibrillation with multiple stable mother rotors. Unlike multiple wavelet fibrillation in which the functional reentry is inherently unstable and nonlocalized and the spontaneous peripheral wavebreaks play a causal role in both initiating and maintaining fibrillation, “mother rotor fibrillation” is driven by a localized source and the peripheral wave breaks are non-causal epiphenomena. However, similar to multiple wave reentry fibrillation, mother rotor fibrillation is purely reentrant and requires a trigger to initiate the original rotor; once initiated, no further triggers are necessary to perpetuate fibrillation.^{11,15}

Recently, several mapping studies have provided clinical evidence of the localized source hypothesis by demonstrating that rotational or focal drivers in localized regions maintain AF, and that AF could be eliminated by directly ablating sites of rotors and focal sources that

exhibit high-frequency, periodic activity, based on either electrogram visual analysis, dominant frequency analysis, or panoramic endocardial mapping using phase analysis (see below).^{16–22}

Mapping human AF. The complexity of AF electrograms, with varying amplitude and morphology as well as spatiotemporal CL variations, poses significant challenges to mapping human AF. Recent clinical studies have demonstrated conflicting mechanisms underlying sustained AF; one source of the discrepancies likely arises from differences in scale (global vs. regional) and spatial resolution of the mapping techniques. A second possible factor is the approach employed to analyze fibrillatory wavefront dynamics, using either phase mapping or activation time.²³

Conventional activation mapping techniques used in the EP lab, which assign a specific time point on the unipolar electrogram as the marker of local activation, cannot be employed during AF; fibrillation electrograms typically are fractionated and low amplitude, and are prone to artifacts.²⁴ Spectral analysis and phase mapping of cardiac potentials have been used by researchers to overcome some of those challenges. Both algorithms derive originally from optical mapping experiments conducted in ex vivo hearts. Although optical mapping provides much higher spatiotemporal resolution and accuracy when tracking rotor formation and maintenance, current optical mapping strategies do not allow panoramic endocardial mapping and require the use of potentially toxic voltage-sensitive dyes that preclude their use for human in vivo studies.^{11,13,25}

The “spectrum” of a signal displays its energy distribution in the frequency domain. Frequency domain analysis can identify the frequency of the highest peak in the spectrum (i.e., “dominant frequency”), which is often used as a surrogate for the average activation rate at a specific location. Hence, spectral analysis can map the distribution of AF frequencies and localize the areas with the highest activation frequencies (i.e., the shortest CLs, dominant frequency), which usually coincide with the location of AF sources (foci or rotors) that maintain AF. Those techniques have demonstrated that AF has significant periodic elements with varying degrees of regularity, and that certain regions of the atria can have higher activation frequencies than other regions, suggesting that these areas can potentially be the drivers that maintain AF and can provide targets of ablation therapy. A limitation of spectral analysis is that frequency domain mapping produces time-averaged frequency information over space, thereby losing the ability to track temporal variations of the signal.^{11,13,24,25}

“Phase” is a measure of where a signal is in its cycle of oscillation at a given point in time. Phase mapping computes oscillations in the signal over its entire duration, independent of its amplitude, and characterizes a temporal signal in its instantaneous phase of the activation/recovery cycle at each time point. Computation of phase involves the transformation of the signal to the phase domain by selecting a specific CL from the temporal signal. Analysis of phase changes over space provides information on the patterns of organization (repetitive activity) and enables visualization of the spatiotemporally distributed patterns of propagation during cardiac fibrillation. Importantly, phase mapping makes it possible to detect rotational wavefronts (rotors) and determines their center of rotation (singularity point) (eFig. 15.2). However, phase mapping has the propensity to introduce false rotors during complex activation patterns, such as wavefront propagation about a line of block.²⁴

In the clinical setting, recent studies employing panoramic atrial mapping during AF have used phase analysis of contact atrial endocardial electrograms from basket electrode catheters (focal impulse and rotor modulation [FIRM], Fig. 15.4) or reconstructed atrial electrograms from body surface recordings (electrocardiogram [ECG] imaging, eFig. 15.3). Those studies demonstrated the presence of atrial driver regions

eFig. 15.2 Varying Activation Patterns Identified in Phase Movies From the Left Atrium of the Sheep Heart. (A) Sequential snapshots show a rotor pivoting around a phase singularity (point where all phases converge). (B) Breakthrough activation pattern. The wave seems on the center of the field of view and propagates outward. *Right*, Key for the different phases of the action potential is color-coded. (From Quintanilla JG, Pérez-Villacastín J, Pérez-Castellano N, et al. Mechanistic approaches to detect, target, and ablate the drivers of atrial fibrillation. *Circ Arrhythmia Electrophysiol.* 2016;9:1–12.)

eFig. 15.3 Phase Mapping of Electrocardiogram Imaging Data Showing Posterior View of Left Atrium During Paroxysmal Atrial Fibrillation. Panel A shows serial snapshots of a single wave emerging out of the left inferior pulmonary vein (PV, white star) and reaching right PVs in 30 milliseconds while it expands radially to the roof and inferior walls. Panel B shows serial snapshots of two successive rotations (white arrows) of a rotor located near the ostia of right PVs. The core of the rotor (white star at the center of rainbow-colored phases of rotor) is seen meandering in a small region in this example. The blue wave indicates the depolarizing front, which makes one full rotation in 160 milliseconds. The phases of wave propagation are color coded using rainbow scale. The blue color represents depolarizing wave and the green represents the end of repolarization. The wavefront can be read by following the blue color. The time (milliseconds) at the bottom of each snapshot represents the moment in the time window when the snapshot was taken. Noninvasive panoramic mapping of human atrial fibrillation mechanisms: a feasibility report. *J Cardiovasc Electrophysiol*. 2013;24:711–717.)

Fig. 15.4 Focal Sources of Atrial Fibrillation Identified by Focal Impulse and Rotor Modulation (FIRM) Mapping. (A) Fluoroscopic view (left anterior oblique) of the multielectrode basket catheter deployed in the left atrium. (B) FIRM mapping shows a left atrial rotor with counterclockwise rotation (from red to blue on the activation time scale with red representing early activation). (C) FIRM mapping shows a left atrial focal impulse originating from electrodes 2 and 3 spline C and D of the basket catheter (red represents early activation with a centrifugal pattern). (From Sommer P, Kircher S, Rolf S, et al. Successful repeat catheter ablation of recurrent longstanding persistent atrial fibrillation with rotor elimination as the procedural endpoint: a case series. *J Cardiovasc Electrophysiol*. 2016;27:274–280.)

with a high prevalence of transient rotors, and suggested that AF is sustained by spiral waves (rotors) or focal sources, or both, which are sufficiently stable in space to be targeted by ablation. Both approaches identified phase singularity points (core of a rotor) as a target for ablation. Elimination of those rotors and focal source could acutely modify or terminate AF and substantially improve ablation outcome. Localized sources can potentially explain modulation of AF by ablation insufficient to limit critical mass and AF termination by localized intervention.^{16–22}

It is important to note that while both ECG imaging and FIRM mapping use phase analysis to determine rotational conduction behavior during AF, detection of rotors using those techniques provides fundamentally different results regarding the spatial behavior of rotors. FIRM mapping demonstrates spatially stable rotors in both atria; many of these rotors are detectable for many seconds up to minutes at the same location. In contrast, ECG imaging techniques show that the reentrant circuits are not spatially stable but meandered substantially throughout the atrium; nevertheless, they recurred repetitively at specific sites that can potentially provide a target for ablation. The reason for the significant discrepancy between the spatial behavior of rotors identified by these different techniques is currently unclear. In a recent study comparing resolution requirements for detection of stationary and meandering rotors found that rotor trajectories can be lost at resolutions for which stable rotors are still identifiable, which may explain differences in findings on rotor stability with basket catheters identifying stable rotors and noninvasive ECG imaging identifying transient meandering rotors.²³

However, despite these data, the rotor paradigm is neither confirmed nor universally accepted, with recent studies raising questions about the efficacy of rotor-targeted ablation. Sufficient spatial resolution is essential for the accurate detection of rotors and focal sources. Although stationary rotors may be identified at coarse resolutions, meandering rotors are lost. While most clinically used catheters offer sufficient spatial resolution to identify and track rotor core location for the range of wavelengths occurring in human AF, mapping catheters with localized coverage (e.g., quadripolar or ring catheters) are not capable of tracking rotors unless the catheter is fortuitously placed over a rotor that does not meander outside the margins of the catheter poles. In contrast, basket catheters provide global coverage. However, the low resolution

of the basket catheters renders them prone to false detections; interpolation of phases is inherently biased toward detection of rotors as the algorithm is devised to demonstrate rotational activity, and focal activation might be displayed as rotational activity if the wavefront reaches the surrounding electrodes sequentially. This can potentially explain, in part, the large incidence of rotors using FIRM mapping, the low AF termination rate with ablation, and poor long-term success for ablating rotors detected by basket catheters. On the other hand, ECG imaging lacks the ability to discern among epicardial breakthroughs, spontaneous depolarizations, and (subcentimeter) microreentry, which are seen as focal activity.^{13,23}

Substrate for Atrial Fibrillation

As noted, AF results from the interplay between a trigger for initiation and a vulnerable EP substrate for maintenance. The fact that most potential triggers do not initiate AF suggests some role for functional and structural substrates in most patients. However, the relative contribution of triggers versus substrate can vary with the clinical context, and the exact nature of the interaction between triggers and substrate remains to be elucidated.

AF commonly occurs in the context of other cardiac or noncardiac pathological conditions, such as valvular disease, hypertension, ischemic heart disease, heart failure, or hyperthyroidism. Depending on the type, extent, and duration of such external stressors, a cascade of time-dependent adaptive, as well as maladaptive, atrial responses develops to maintain homeostasis (so-called “atrial remodeling”), including changes at the ionic channel level, cellular level, extracellular matrix level, or a combination of these, which result in electrical, functional, and structural consequences.

A hallmark of atrial structural remodeling is atrial dilation, often accompanied by a progressive increase in interstitial fibrosis. Atrial arrhythmias, especially AF, are the most common manifestations of electrical remodeling. Increased dispersion in atrial refractoriness and inhomogeneous dispersion of conduction abnormalities, including block, slow conduction, and dissociation of neighboring atrial muscle bundles, are key elements in the development of the substrate of AF. Importantly, different pathological conditions can be associated with a different set of remodeling responses in the atria.

Even in the setting of the AF occurring in the absence of apparent structural heart disease, there is accumulating evidence that occult abnormalities (e.g., patchy fibrosis, inflammatory infiltrates, loss of myocardial voltage, conduction slowing, altered sinus node function, and vascular dysfunction) can be observed and likely represent an early stage of atrial remodeling contributing to the substrate of AF.

Atrial Electrophysiological Properties

In normal atrial cardiomyocytes, phase 0 of the action potential is mediated by the rapidly activating sodium (Na^+) current (I_{Na}). These potentials are called *fast response* potentials (see Chapter 1). As a result, the atrium has several properties that permit the development of very complex patterns of conduction and an extremely rapid atrial rate, as seen in AF. The action potential duration is relatively short, and reactivation can occur partially during phase 3 and usually completely within 10 to 50 milliseconds after return to the diastolic potential. The refractory period shortens with increasing rate, and very rapid conduction can occur.

Patients with AF and no apparent structural heart disease appear to have increased dispersion of atrial refractoriness, which correlates with enhanced inducibility of AF and spontaneous episodes. Some patients have site-specific dispersion of atrial refractoriness and intraatrial conduction delays resulting from nonuniform atrial anisotropy.

Atrial Fibrosis

Atrial fibrosis plays an important role in the pathophysiology of AF. Atrial fibrosis results from various cardiac insults that share common fibro-proliferative signaling pathways. Fibrotic myocardium exhibits slow and inhomogeneous conduction, with spatial “nonuniform anisotropic” impulse propagation, likely secondary to reduced intercellular coupling, discontinuous branching architecture, and zigzagging circuits. When combined with inhomogeneous dispersion of refractoriness within the atria, conduction block provides milieu necessary for the development of reentry. The greater the slowing of conduction velocity in fibrotic myocardium, the shorter the anatomic circuit needed to sustain a reentrant wavelet. In fact, reentrant circuits need be only a few millimeters in length in discontinuously conducting tissue. Thus atrial regions with advanced fibrosis can harbor local sources for AF. Such a hypothesis would not preclude the remainder of the atria from showing fibrillatory conduction or functional reentrant waves.^{7,26–29}

Increased atrial fibrosis is a manifestation of the normal aging process as well as various pathological conditions such as hypertension, coronary artery disease, heart failure, and sleep apnea. Increased atrial fibrosis has been demonstrated even in patients with so-called “lone” or “idiopathic” AF, suggesting that AF in these patients potentially represents an arrhythmic manifestation of “fibrotic atrial myopathy.” The strong association of sinus node dysfunction (SND) and AF (the bradycardia-tachycardia syndrome) also suggests that replacement of atrial myocytes by fibrosis likely plays an important part in the pathogenesis of AF, although in some instances the bradycardia component is a functional response to the tachycardia. Recent studies using delayed-enhancement cardiovascular magnetic resonance (CMR) imaging and electroanatomic voltage mapping demonstrated that the extent and distribution of the fibrotic atrial changes can vary widely among patients with AF. Nonetheless, a higher degree of fibrosis often is observed in patients with persistent AF versus paroxysmal AF. In addition, atrial fibrosis defined by delayed-enhancement CMR was found to be independently associated with AF recurrence in patients undergoing catheter ablation procedures.^{7,27,30}

Importantly, AF itself seems to produce various alterations of atrial architecture that further contribute to atrial remodeling, mechanical dysfunction, and perpetuation of fibrillation. Longstanding AF results

in loss of myofibrils, accumulation of glycogen granules, disruption in cell-to-cell coupling at gap junctions, and organelle aggregates.²⁶

Changes in AF characteristics during evolving fibrosis also have a direct impact on why electrical or drug treatment ultimately fails to achieve conversion to NSR. In the markedly fibrotic and discontinuous atrial tissue, characterized by discontinuous anisotropy, marked degree of gap junctional uncoupling, and fiber branching, the safety factor for propagation is higher than in normal tissue. Hence, blocking of the Na^+ current to the same degree as is necessary for the termination of functional reentry may not terminate reentry caused by slow and fractionated conduction in fibrotic scars of remodeled atria. Conduction in discontinuous tissue is mostly structurally determined and leads to excitable gaps behind the wavefronts. If a gap is of critical size, the effectiveness of drugs that prolong atrial refractoriness will be limited. Furthermore, scar tissue is likely to exhibit multiple entry and exit points and multiple sites at which unidirectional block occurs. This can potentially lead to activity whose appearance in local extracellular electrograms changes from beat to beat, as well as beat-to-beat CL variability. Although such regions can be expected to respond to defibrillation, AF can resume after extrasystoles or normal sinus beats immediately after conversion, with unidirectional block recurring because of scar.

Atrial Stretch

Atrial stretch and dilation can play a role in the development and persistence of AF. Clinically, AF episodes occur more frequently in association with conditions known to cause elevated LA pressure and atrial stretch, such as acutely decompensated systolic or diastolic heart failure. In addition, the echocardiographic LA volume index and restrictive transmitral Doppler flow patterns are strong predictors of the development of AF.

The structure of the dilated atria can potentially have important EP effects related to stretch of the atrial myocardium (so-called “electromechanical feedback”). Acute atrial stretch reduces the atrial refractory period and action potential duration and depresses atrial conduction velocity, potentially through a reduction of cellular excitability by the opening of stretch-activated channels or changes in cable properties (membrane resistance, capacitance, core resistance). Regional stretch for less than 30 minutes activates the immediate early gene program, thus initiating hypertrophy and altering action potential duration in affected areas. Moreover, acutely altered stress and strain patterns augment the synthesis of angiotensin II, which induces myocyte hypertrophy. Angiotensin II can contribute to arrhythmogenic electrical dispersion by regionally increasing L-type calcium (Ca^{2+}) current (I_{CaL}) and decreasing the transient outward potassium (K^+) current (I_{to}). Altered stretch of atrial myocytes also results in opening of stretch-activated channels, increasing G protein-coupled pathways. This leads to increased protein kinase A and C activity, and enhanced I_{CaL} through the cell membrane, and increased release of Ca^{2+} from the sarcoplasmic reticulum, thus promoting afterdepolarizations and triggered activity. Furthermore, acute stretch can promote an increase in dispersion of refractoriness and spatial heterogeneity by causing conduction block and potentially contributing to the development of AF. These alterations occur nonuniformly because stretch is greater in areas of thin versus thick atrial myocardium.

In addition, chronic atrial stretch, as a result of AF and several conditions associated with AF, can promote atrial fibrosis via the activation of multiple profibrotic and hypertrophic signaling pathways.

Inflammation

There is increasing evidence that implicates inflammation (and its downstream effects, including atrial fibrosis) in the pathogenesis of

AF. Clinically, AF occurs frequently in the setting of inflammatory states such as cardiac surgery and acute pericarditis. In addition, the levels of inflammatory biomarkers (C-reactive protein [CRP] and interleukin-6 [IL-6]) are significantly increased in patients with AF, findings suggesting the presence of systemic inflammation in these patients. Elevation of the levels of CRP and IL-6 has been shown to predict future development, recurrence, and burden of AF. There is also evidence suggesting that inflammation is involved in electrical and structural atrial remodeling. Furthermore, inflammation appears to increase the inhomogeneity of atrial conduction directly, potentially via disruption of expression of connexin proteins, leading to impaired intercellular coupling.³¹

It is also likely that inflammation can be a consequence of AF. CRP levels decrease following restoration of NSR. Rapid atrial activation in AF results in Ca^{2+} overload in atrial myocytes that can potentially result in cell death, which induces a low-grade inflammatory response. The inflammation, in turn, can induce healing and reparative fibrosis that likely enhance remodeling and promote perpetuation of the arrhythmia.

Currently, the exact role of inflammation in AF is poorly defined, and it remains unclear whether inflammation is actually involved in the mechanisms underlying AF or whether it is simply an epiphenomenon. Although therapies directed at attenuating the inflammatory burden (e.g., glucocorticoids, statins, and angiotensin II inhibitors) appear promising, early clinical trials do not support a significant benefit.³²

Atrial Remodeling in Atrial Fibrillation

AF is a progressive arrhythmia. In 14% to 24% of patients with paroxysmal AF, persistent AF develops, even in the absence of progressive underlying heart disease. Furthermore, conversion of AF to NSR, electrically or pharmacologically, becomes more difficult when the arrhythmia has been present for a longer period. In fact, the arrhythmia itself results in a cascade of electrical and structural changes in the atria that are themselves conducive to the perpetuation of the arrhythmia ("AF begets AF"), a process known as remodeling. Recurrent AF can potentially lead to irreversible atrial remodeling and eventually permanent structural changes that account for the progression of paroxysmal to persistent and finally to permanent AF, characterized by the failure of electrical cardioversion and pharmacological therapy to restore and maintain NSR. Even after cessation of AF, these abnormalities persist for periods that vary in proportion to the duration of the arrhythmia.³³

Changes in atrial EP features induced by AF can occur through alterations in ion channel activities that cause partial depolarization and abbreviation of atrial refractoriness. These changes promote the initiation and perpetuation of AF (electrical remodeling) and the modification of cellular Ca^{2+} handling, which causes contractile dysfunction (contractile remodeling), as well as atrial dilation with associated structural changes (structural remodeling). Experimentally, electrical and contractile remodeling begins shortly after the onset of AF, with a parallel decrease in both atrial refractory period and contractility over the first minutes of AF. This is followed by further abbreviation in atrial refractoriness and increase in atrial dimensions over the following days. Structural changes follow a much slower time course, likely starting after several weeks.^{34,35}

Electrical Remodeling

Electrical remodeling results from the high rate of electrical activation. The EP changes typical of atrial myocytes during AF include shortening of the action potential duration and atrial refractory period, and reduction in the amplitude of the action potential plateau. Furthermore, AF results in deficiency in the ability of the repolarization time course (action potential duration) to adapt to changes in rate

("abnormal restitution"); consequently, the atrial refractory period fails to lengthen appropriately at slow rates (e.g., with return to NSR). These changes can contribute to the stability of a longer lasting form of AF because, according to the multiple wavelet theory, a short wavelength results in smaller wavelets, which increase the maximum number of wavelets, given a certain atrial mass. Tachycardia-induced changes in refractoriness are spatially heterogeneous, and there is increased variability both within and among various atrial regions, which can promote atrial vulnerability and AF maintenance and provide a substrate for reentry.

The mechanisms for electrical remodeling and shortening of the atrial refractory period are not entirely clear. Several potential explanations exist, including ion channel remodeling, angiotensin II, and atrial ischemia. The principal components of electrical remodeling include reduction in the L-type Ca^{2+} current (ICaL), rectifier background K^{+} current (IK1), and constitutive acetylcholine-regulated K^{+} current (IKACH), and abnormal expression and distribution of the gap junctions.³³

Downregulation of ICaL seems to be responsible for shortening of the atrial action potential, whereas a decrease in Ito is considered to result in loss of physiological rate adaptation of the action potential. The fast atrial rate during AF causes accumulation of intracellular Ca^{2+} . The reduction in ICaL can be explained by a decreased expression of the L-type Ca^{2+} channel $\alpha 1\text{C}$ subunit, likely as a compensatory mechanism to minimize the potential for cytosolic Ca^{2+} overload secondary to increased Ca^{2+} influx during the rapidly repetitive action potentials during AF. Verapamil, an L-type Ca^{2+} channel blocker, was shown to attenuate electrical remodeling and hasten complete recovery without affecting inducibility of AF, whereas intracellular Ca^{2+} overload, induced by hypercalcemia or digoxin, enhances electrical remodeling. Electrical remodeling can be attenuated by the sarcoplasmic reticulum's release of the Ca^{2+} antagonist ryanodine, a finding suggesting the importance of increased intracellular Ca^{2+} to the maladaptation of the atrial myocardium during AF.³³

Angiotensin II may also be involved in electrical remodeling, and angiotensin II inhibitors may prevent the remodeling process. Angiotensin-converting enzyme inhibitors reduce the incidence of AF in patients with left ventricle (LV) dysfunction after myocardial infarction (MI) and in patients with chronic ischemic cardiomyopathy. Atrial ischemia is another possible contributor to electrical remodeling and shortening of the atrial refractory period via activation of the $\text{Na}^{+}\text{-H}^{+}$ exchanger.

More recently, microRNAs (miRNAs or miRs), a group of small noncoding RNA molecules that negatively regulate gene expression, were found to have an important role in a wide range of electrical and structural atrial remodeling processes.^{34,36} Furthermore, experimental studies showed that the rapid rates of AF can lead to autonomic atrial remodeling, with heterogeneous increase in atrial sympathetic innervation, which can potentially promote enhanced automaticity, triggered activity, and spatially heterogeneous abbreviation of refractoriness.⁷

Furthermore, persistent AF can result in other changes within the atria, including gap junctional remodeling, manifest as an increase in the expression and distribution of connexin 43 and heterogeneity in the distribution of connexin 40, both of which are intercellular gap junction proteins.

Contractile and Structural Remodeling

Sustained AF has also been associated with structural changes such as myocyte hypertrophy, myocyte death, tissue fibrosis, impaired atrial contractility, and atrial stretch and dilation. Atrial dilation increases electrical instability by shortening the effective refractory period and slowing atrial conduction. These structural changes, many of which

probably are irreversible, appear to occur over periods of weeks to months.³³

Cellular remodeling is caused by the apoptotic death of myocytes with myolysis. AF results in marked changes in atrial cellular substructures, including loss of myofibrils, accumulation of glycogen, changes in mitochondrial shape and size, fragmentation of sarcoplasmic reticulum, and dispersion of nuclear chromatin.

Contractile remodeling is likely caused by downregulation of ICaL (resulting in reduced release of Ca^{2+} during systole), as well as myolysis (loss of sarcomeres). Contractile remodeling can potentially cause thrombus formation and atrial dilation. Contractile remodeling starts early after onset of AF, and its recovery generally takes longer than reversal of electrical remodeling, likely because of the time it takes for the atria to replace lost sarcomeres.³⁵

In addition to remodeling of the atria, the sinus node can undergo remodeling, resulting in SND and bradyarrhythmias caused by reduced sinus node automaticity or prolonged sinoatrial conduction. The phenomenon of sinus node remodeling likely contributes to the episodes of bradycardia seen in the tachycardia-bradycardia syndrome and may reduce sinus rhythm stability and increase the stability of AF. As mentioned earlier, elements of the sinus bradycardia appear to be functionally reversible if the tachycardia is prevented.

Studies suggest that the PVs are more susceptible to electrical alterations resulting from AF than the atria. Although the PVs display significantly longer refractory periods at baseline than the atria, they exhibit more prominent shortening of refractoriness after a brief episode of pacing-induced AF. Moreover, the short-term presence of AF does influence PV EP properties by slowing the conduction velocity without affecting the conduction times of the atria. Structural changes in the atria after remodeling, such as stretch, can also lead to increased PV activity. Atrial stretch can lead to increased intraatrial pressure, causing a rise in the rate and spatiotemporal organization of electrical waves originating in the PVs. These changes imply that electrical and structural remodeling increases the likelihood of ectopic PV automaticity and AF maintenance.

Tachycardia-induced atrial remodeling can potentially underlie various clinically important phenomena, such as the tendency of patients with other forms of supraventricular arrhythmias to develop AF, the tendency of AF to recur early after electrical cardioversion, the resistance of longer duration AF to antiarrhythmic medications, and the tendency of paroxysmal AF to become persistent.

If NSR is restored within a reasonable time period, EP changes and atrial electrical remodeling appear to normalize gradually, atrial size decreases, and atrial mechanical function is restored. These observations lend support to the idea that the negative downhill spiral in which AF begets AF can be arrested with NSR that perpetuates NSR, and restoration of NSR may forestall progressive remodeling and the increase in duration and frequency of arrhythmic episodes by reverse remodeling.

Role of Autonomic Nervous System in Atrial Fibrillation

Cardiac function is modulated by both the extrinsic and the intrinsic cardiac autonomic nervous systems. The extrinsic (central) system is composed of sympathetic and parasympathetic components, and includes neurons in the brain and spinal cord and nerves directed to the heart. The intrinsic system is composed of a large network of autonomic cardiac ganglia buried throughout the epicardial fat within the pericardial space and in the ligament of Marshall. Groups of several cardiac ganglia comprise plexuses that coalesce in specific locations, and different groups of ganglia have different sites of innervation throughout the heart. Atrial ganglia contain afferent neurons from the atrial myocardium and from the central autonomic nervous system, and

efferent cholinergic and adrenergic neurons, with heavy innervation of the PV myocardium and the atrial myocardium surrounding the ganglionic plexuses. In addition, an extensive array of interconnecting neurons creates a communication network among the different ganglionic plexuses, as well as between the ganglionic plexuses and the atrium and PV myocardium. The intrinsic system receives input from the extrinsic system and but acts independently to modulate numerous cardiac functions, including automaticity, contractility, and conduction.³⁷

Several studies have demonstrated that both divisions of the autonomic nervous system are involved in the initiation, maintenance, and termination of AF, with a predominant role of the parasympathetic system. Enhanced sympathetic activity shortens the atrial refractory period and also increases sarcoplasmic reticulum calcium release in the atrium and PV myocardium, promoting after-depolarization-related PACs and atrial tachycardia (AT), which in turn can initiate AF.^{38,39} On the other hand, increased vagal tone is frequently involved in the onset of AF in patients with structurally normal hearts. Parasympathetic stimulation results in nonuniform shortening of the atrial effective refractory periods, thereby setting up substrate for reentry, promoting the initiation and perpetuation of AF. Vagal stimulation can also lead to the emergence of focal triggers in the atrium. It is important to note that imbalances in the intrinsic cardiac nervous system (rather than an enhanced tone per se) are thought to be involved in the pathogenesis of AF. A shift toward an increase in sympathetic tone or toward a loss of vagal tone has been observed before postoperative paroxysmal AF, whereas a shift toward vagal predominance was observed in young patients with nocturnal episodes of paroxysmal AF.^{40,41}

The electrical properties of the PVs also are modulated by changes in autonomic tone. Anatomic studies revealed that the PVs and the adjoining posterior LA have a unique autonomic profile that differs from the rest of the atria, which likely contributes to the genesis of both focal triggers and sustained microreentry in this region. Ganglionated plexuses cluster within fat pads at the PV entrances and heavily innervate each of the myocardial sleeves of the four PVs. Activation of the ganglionic plexuses at the PV-LA junction promotes AF by a combined parasympathetic and sympathetic action.^{41,42}

Studies suggest that the extrinsic autonomic input to the heart (i.e., from the brain and spinal cord) exerts inhibitory control over the ganglionated plexuses and that attenuation or loss of this control would allow the ganglionated plexuses to become hyperactive. The ganglionic plexuses function as “integration centers” that modulate autonomic innervation. Hyperactivity of ganglionic plexuses can be proarrhythmic while low-level activity may be antiarrhythmic. Recent evidence suggests that noninvasive cardiac autonomic neuromodulation therapies (such as transcutaneous electrical stimulation of the vagus nerve) suppress ganglionated plexus activity, with consequent increased effective refractory period of the atrial and PV myocardium and suppressed AF inducibility. Other approaches to modulation of the extrinsic cardiac autonomic nervous system (e.g., renal sympathetic denervation and ganglion stellatum ablation) are being investigated for antiarrhythmic treatment. Furthermore, ablation of ganglionated plexuses located at the atrial entrances or antra of the PVs can potentially abolish or reduce AF inducibility.⁴³

Role of the Pulmonary Veins in Atrial Fibrillation

There is little controversy now that the PVs play a major role in triggering and maintaining AF, as established by animal and human models, especially in the setting of paroxysmal AF. Fibrillatory conduction is likely initiated by rapid discharges from one or several focal sources within the atria; in most patients with AF (94%), the focus is in one of the PVs (see Fig. 15.2). Extra-PV sites can also trigger AF, but this

occurs in a minority of cases, likely no more than 10% of patients. AF is also perpetuated by microreentrant circuits, or rotors, that exhibit high-frequency periodic activity from which spiral wavefronts of activation radiate into surrounding atrial tissue. Conduction becomes slower and less organized with increasing distance from the rotors, likely because of atrial structural remodeling, resulting in fibrillatory conduction. Interestingly, the dominant rotors in AF appear to cluster primarily in the junction between the LA and PVs. One study also demonstrated that the PV-LA region has heterogeneous EP properties capable of sustaining reentry. As noted earlier, autonomic inputs can be important in triggering and maintaining AF, and many of these inputs are clustered close to the PV-LA junction.

The role of PVs in the initiation and perpetuation of persistent AF seems less prominent than in the setting of paroxysmal AF, likely secondary to the electrical and structural remodeling associated with persistent AF. Non-PV triggers occur more commonly, and the reentry sites required for AF perpetuation are more often found outside the PV-LA junction in persistent AF than in paroxysmal AF.

Pulmonary Vein Anatomy

PVs can have variable anatomy. Most hearts examined are found to have four PVs with distinct ostia. The PV ostia are ellipsoid with a longer superoinferior dimension, and funnel-shaped ostia are frequently noted in patients with AF. The right superior PV lies just behind the SVC or RA, and the right inferior PV projects horizontally. The left superior PV lies between the LA appendage (LAA) and the descending aorta, and the left inferior PV courses near the descending aorta (Fig. 15.5). The superior PVs project forward and upward, whereas the inferior PVs project backward and downward. PVs are larger in patients with AF than in normal subjects, in men than in women, and in persistent versus paroxysmal AF.

Significant variability of PV morphologies can be observed in 40% of patients undergoing AF ablation, including: (1) common ostium (in approximately 25% of patients; Fig. 15.6) of left-sided or, less frequently, right-sided PV; (2) supernumerary right PVs (right middle PV is observed in 8% to 29% of patients; see Fig. 15.6); (3) anomalous PVs arising from the LA roof; and (4) multiple ramification and early branching (especially of the right inferior PV).

The PVs are covered by myocardial sleeves formed by one or more layers of myocardial fibers oriented in a circular, longitudinal, oblique, or spiral direction. These sleeves, continuing from the LA into the PV, vary from 2 to 25 mm in length (mean, 13 mm). The length of the myocardial sleeves usually has a distinctive distribution; superior PVs have longer and better developed myocardial sleeves than inferior PVs, which can potentially explain why arrhythmogenic foci are found more often in the superior PVs than in the inferior PVs. It should be noted that all PVs in all individuals have such myocardial sleeves, regardless of the presence or absence of AF.

The walls of the PVs are composed of a thin endothelium, a media of smooth muscle, and a thick outer fibrous adventitia. The transition from atrial to venous walls is gradual because the myocardial sleeves from the LA overlap with the smooth muscle of the venous wall. The myocardial sleeves are thickest at the venoatrial junction (mean, 1.1 mm) and then gradually taper distally. Furthermore, the thickness of the sleeves is not uniform, with the inferior walls of the superior veins and the superior walls of the inferior veins having the thicker sleeves. Throughout the PV, and even at the venoatrial junction, there are gaps in the myocardial sleeves mainly composed of fibrous tissue. The arrangement of the myocyte bundles within the sleeves is rather complex. There appears to be a mesh-like arrangement of muscle fascicles made up of circularly oriented bundles (spiraling around the long axis of the vein) that interconnect with bundles that run in a longitudinal orientation

(along the long axis of the vein). Such an arrangement, together with the patchy areas of fibrosis seen, can be relevant to the role of the PVs in the initiation of AF.

Electrophysiology of Pulmonary Vein Musculature

As noted, the PVs play a crucial role in the initiation and, in some cases, maintenance of AF. However, it is not clear what makes this region so susceptible to the arrhythmia. There are, at present, limited data available on the ionic mechanisms that underlie the arrhythmogenicity of PVs. Detailed mapping studies have suggested that reentry within the PVs is most likely responsible for their arrhythmogenicity, although abnormal automaticity and triggered activity have also been observed. However, the rarity with which AF continues within the PV after electrical isolation (see later) calls into question whether the PVs are adequate in themselves to maintain AF.

The EP features of the PV, with its distinct area of slow conduction, decremental conduction, nonuniform anisotropy, and heterogeneous repolarization, create potential substrates for reentry. The heterogeneous fiber orientation in the transition from the LA to the PV sleeve results in unique conduction properties in this area. It is possible that the complex arrangement of muscle fibers within the myocardial sleeves and the uneven distribution of interspersed connective and adipose tissue account for the greater degree of decremental conduction observed in the myocardial sleeves than in the LA and for the heterogeneity in conduction properties and refractory periods among the fascicles in the myocardial sleeves. Therefore the fractionation of PV potentials commonly observed during premature stimulation (which usually indicates local slowing of conduction) is consistent with anisotropic properties that can be attributable to the complex arrangement of muscle fascicles within the myocardial sleeves.

Several studies suggested that abnormal automaticity or triggered activity, either alone or in combination with the reentrant mechanisms described previously, can play a role in the initiation of AF. These studies suggested that the propensity of PVs to exhibit abnormal automaticity or triggered activity is enhanced by pathological conditions. Further work also implicated LA posterior wall in the genesis of AF. Studies suggested that the PVs, together with the posterior LA, have an important role in the persistent form of AF. However, the nature of the relationship between this arrhythmogenic region and the pathological conditions that provide a substrate for AF has not been elucidated. Whether the critical region is the posterior LA, the PVs, or both, has been the source of ongoing debate.

Pulmonary Vein Tachycardia Versus Pulmonary Vein Fibrillation

In patients with paroxysmal AF originating from the PVs, a wide spectrum of atrial arrhythmias can coexist. Extensive monitoring frequently documents coexisting paroxysms of AT and AF. Furthermore, patients with paroxysmal AF usually have multiple foci in multiple PVs, and many of these foci originate distally in those veins.

In patients whose only clinical arrhythmia is PV AT, the clinical course is more comparable to that in patients with AT from other anatomic locations than to patients with PV AF. Those patients demonstrate a largely focal process, without evidence of a more progressive and diffuse disease as observed in the population with paroxysmal AF, and they have no tendency to develop further atrial arrhythmias during long-term follow-up. Notably, when patients with PV AT present with recurrence, in almost all cases this is from the original focus. In contrast, patients with paroxysmal AF have recurrences from foci in other PVs and from within the body of the LA. Importantly, in most patients with PV AT, the focus is located at the ostium of the vein (or within 1 cm of the ostium), rather than from further distally

Fig. 15.6 Cardiac Computed Tomography Angiogram (Posteroanterior and Cardioscopic Views) of the Left Atrium and Pulmonary Veins (PVs). (A and B) The left-sided PVs share a common ostium. (C and D) Three PVs are observed on the right side. LAA, Left atrial appendage; LCPV, left common PV; LSPV, left superior PV; RIPV, right inferior PV; RMPV, right middle PV; RSPV, right superior pulmonary vein.

because of the significant overlap in the arrhythmia characteristics (initiation, response to drugs).

Genetics in Atrial Fibrillation

It is increasingly recognized that a widespread heritable component underlies AF, especially in patients without apparent risk factors. Studies have shown that at least 5% of all patients with AF and 15% to 20% of those with AF and structurally normal hearts had a positive family history. Family history of AF is associated with a 40% increased risk of first-degree relatives developing AF. The association between family history and risk of AF development is stronger with increased numbers of affected first-degree relatives and younger age.⁹

Several genes and genomic regions linked to AF and its substrate have been identified in families, individuals, and different populations. Genetic factors play a critical role in modulating the risk of the arrhythmia both in rare families with mendelian patterns of AF inheritance and in the general population. Although familial AF may be a monogenetic disorder, nonfamilial AF may be a multigenetic disease in which genetic factors interact with environmental variables.⁹

Classic mendelian genetics and candidate gene approaches have identified AF-causing mutations in genes encoding cardiac ion channels, cardiac gap junctions, signaling molecules, as well as transcription factors. Those channelopathies are commonly associated with other phenotypic manifestations, such as the long QT, short QT, or Brugada syndromes, as well as inherited cardiomyopathies.⁴⁴ AF is prevalent in cardiac channelopathies and can be the presenting feature in some patients. Studies demonstrated AF prevalence of 2% to 29% in long QT syndrome, 6%

to 53% in Brugada syndrome, 18% to 70% in short QT syndrome, and 11% to 37% in patients with catecholaminergic polymorphic ventricular tachycardia (VT).⁴⁵ These genetic variants promote AF by either abbreviating atrial refractoriness (facilitating reentry), prolonging atrial action potential duration (facilitating triggered activity), or impairing intercellular coupling (resulting in conduction heterogeneity).^{30,46}

It is noteworthy that a recent study described a rare autosomal recessive atrial cardiomyopathy characterized by progressive fibrosis of the atrial myocardium and clinically manifesting with atrial arrhythmias (including AF), atrial dilation, and potential atrial electrical standstill.³⁰

Furthermore, whole-exome sequencing (WES) and genome-wide association studies (GWASs) have identified multiple single-nucleotide polymorphisms (SNPs), a type of common genetic variant, as genetic risks associated with AF in the population. The precise molecular mechanisms underlying these variants remain unclear, owing partly to their presence in noncoding areas of the genome with no known effect on protein expression or function. SNPs presumably act as promoters or enhancers of proximate genes. The closest genes identified with various SNPs are involved in diverse functions, such as in encoding of transcription factors, cytoskeletal and scaffolding proteins, and ion channels.^{44,47–49}

EPIDEMIOLOGY

AF is the most common sustained arrhythmia encountered in clinical practice, accounting for approximately one-third of hospitalizations for cardiac rhythm disturbances. The worldwide age-adjusted prevalence of AF is estimated at 0.596% in men and 0.373% in women,

approximately 33 million people. Each year more than 5 million people develop AF worldwide. The prevalence of AF in the general population in the Western world has been estimated at 0.5% to 2%, although the true prevalence of AF is probably higher given the common occurrence of asymptomatic (subclinical) AF. Furthermore, the frequency of AF is progressively increasing in the general population, likely due to increased longevity and the success in reducing overall cardiovascular mortality, as well as increased prevalence of risk factors for AF (such as hypertension and obesity). In 2010, the prevalence of AF in the United States was estimated to be between 2.7 and 6.1 million. This is expected to rise to about 5.6 to 12 million in 2050. In Europe, AF affects about 8 million people and this number is expected to rise to 18 million by 2060.⁵⁰

AF is a progressive disease. More than half of individuals who experience an initial episode of AF will eventually develop recurrent AF, typically within the first 2 years of follow-up. AF progresses from paroxysmal to persistent (despite antiarrhythmic therapy) in approximately 10% at 1 year, in 25% to 30% at 5 years, and in more than 50% beyond 10 years. Furthermore, progression from paroxysmal and persistent AF to permanent AF occurs in up to 34% of patients at 4 years after the initial diagnosis. Maintenance of NSR becomes progressively more difficult as the duration of persistent AF increases. Only 40% to 60% of patients with persistent AF of less than 1 year's duration remain in NSR 1 year after initiation of antiarrhythmic drug therapy, despite multiple cardioversions; whereas patients with persistent AF of more than 3 year's duration have only a 15% likelihood of long-term sinus rhythm. Increased age, diabetes, heart failure, chronic pulmonary disease, and hypertension are among potential predictors of progression to permanent AF. AF occurring in otherwise healthy patients is less likely to progress.⁵¹ Also, AF patients treated with catheter ablation exhibit a substantially lower risk of progression of the arrhythmia.^{9,52}

AF is independently associated with significantly increased morbidity and mortality, including a fivefold increased risk for stroke, a twofold increased risk for dementia, a threefold risk for heart failure, and a twofold increased risk for MI. The mortality rate of patients with AF is approximately double that of patients in NSR and is linked to the severity of underlying heart disease and associated comorbidities.⁵³ Cardiac causes (sudden cardiac death [SCD], heart failure, and MI) account for almost one-half of deaths in anticoagulated patients with AF, whereas stroke and bleeding only account for approximately 6% of all deaths each as the principal cause. The risk of death appears higher in the presence of heart failure, renal insufficiency, diabetes, advanced age, and male gender.^{9,44,54,55}

Atrial Fibrillation Risk Prediction

Several prediction models for new-onset AF have been proposed to help identify high-risk individuals and serve as a benchmark to test potential novel risk factors. The Framingham Heart Study (FHS) and the Atherosclerosis Risk in Communities (ARIC) Study each developed a risk for the prediction of AF. More recently, the Cohorts for Heart and Aging Research in Genomic Epidemiology–Atrial Fibrillation (CHARGE-AF) consortium developed and validated a simple risk model for prediction of incident AF using pooled data (greater than 26,000 individuals) from prospective cohort studies, including the Cardiovascular Health Study, FHS, and ARIC. The variables used in the CHARGE-AF risk prediction score include: age, race, height, weight, systolic blood pressure, diastolic blood pressure, current smoking, use of antihypertensive medication, diabetes, history of MI, and history of heart failure. In addition to these variables, the “augmented” CHARGE-AF prediction score also incorporates the PR interval and ECG-derived LV hypertrophy.^{1,56,57}

Clinical Risk Factors Predisposing to Atrial Fibrillation

AF can be related to a transient reversible cause, such as thyrotoxicosis, acute MI, acute pericarditis, recent cardiac surgery, acute pulmonary disease, alcohol intake, or electrocution. In these cases, AF generally disappears after treatment of the underlying precipitating condition.

AF is thought to be secondary to underlying structural heart disease in more than 70% of patients and is the final arrhythmic expression of a diverse family of diseases. AF derives from a complex continuum of predisposing factors that appear to involve disease processes that contribute to the triggering of AF (e.g., sympathetic and parasympathetic nervous systems [neurogenic AF], predisposing arrhythmias, or ectopic foci in PVs), increase atrial distention (e.g., valvular heart disease, hypertension, and heart failure), decrease the ratio of atrial myocyte to fibrotic tissue, possibly including an increased rate of apoptotic cell death (e.g., hypertension and ischemic heart disease), disrupt intercellular communications (e.g., pericarditis and edema), increase inflammatory mediators (e.g., pericarditis and myocarditis), or alter energy and redox states that modulate the function of ion channels and gap junctions. Table 15.2 lists cardiovascular and other conditions independently associated with AF.

The most frequent causes of acute AF are MI and cardiothoracic surgery. The most common clinical risk factors for chronic AF are hypertension and ischemic heart disease, with the subset of patients having congestive heart failure most likely to experience the arrhythmia. In the developing world, hypertension and rheumatic valvular (usually mitral) and congenital heart diseases are the most commonly related conditions.^{55,58,59}

The presence of SND also predicts an increased risk for AF. Atrial high-rate episodes (usually indicative of AF or AFL) lasting longer than 5 minutes were noted in 29% of the patients receiving pacemakers for SND but with no prior history of AF.

In younger patients, approximately 30% to 45% of paroxysmal cases and 20% to 25% of persistent cases of AF occur in the absence of any chronic or acute risk factors for the arrhythmia, a condition historically referred to as lone AF. However, given the ambiguous definition in the literature and lack of mechanistic or clinical utility, categorizing AF as “lone” or “idiopathic” is potentially confusing and should not be used to guide therapeutic decisions.⁵

Unmodifiable Risk Factors

Age. The prevalence of AF increases with advancing age. AF is uncommon in childhood except after cardiac surgery. AF occurs in less than 1% of individuals younger than 60 years, but in approximately 6% of those older than 65 years, and in more than 10% of those older than 80 years. The median age of patients with AF is approximately 75 years. About 75% of patients with AF are 65 years of age or older, and 45% of patients with AF are 75 years of age or older.⁵⁹ In adults 55 years of age and older, the lifetime risk of the development of AF is approximately 24% in men and 22% in women.⁹

Gender. The age-adjusted annual incidence of AF is higher in men compared with women (3.8 vs. 1.6 per 1000 person-years). Similarly, the age-adjusted prevalence of AF is higher in men than in women (10.3% vs. 7.4% in adults aged greater than or equal to 65 years). However, gender-related differences in AF incidence and prevalence appear to be related to other risk factors. One report found that, after adjusting for AF-related risk factors, male gender was no longer an independent risk factor for AF. Of note, the lifetime risk for AF is similar between men and women despite higher AF incidence in men, likely related to the shorter life expectancy in men.⁹

Race. The age-adjusted risk of developing AF is higher in whites as compared to blacks, Asians, and Hispanics.⁹

TABLE 15.2 Cardiovascular and Other Conditions Independently Associated With Atrial Fibrillation

Characteristic/Comorbidity	Association With AF
Genetic predisposition (based on multiple common gene variants associated with AF) ⁶⁴	HR range 0.4–3.2
Older age ¹⁹	HR:
50–59 years	1.00 (reference)
60–69 years	4.98 (95% CI 3.49–7.10)
70–79 years	7.35 (95% CI 5.28–10.2)
80–89 years	9.33 (95% CI 6.68–13.0)
Hypertension (treated) vs. none ¹⁹	HR 1.32 (95% CI 1.08–1.60)
Heart failure vs. none ¹⁹	HR 1.43 (95% CI 0.85–2.40)
Valvular heart disease vs. none ²⁰⁵	RR 2.42 (95% CI 1.62–3.60)
Myocardial infarction vs. none ¹⁹	HR 1.46 (95% CI 1.07–1.98)
Thyroid dysfunction ^{206,207}	(reference: euthyroid)
Hypothyroidism	HR 1.23 (95% CI 0.77–1.97)
Subclinical hyperthyroidism	RR 1.31 (95% CI 1.19–1.44)
Overt hyperthyroidism	RR 1.42 (95% CI 1.22–1.63)
Obesity ^{19,208}	HR:
None (BMI <25 kg/m ²)	1.00 (reference)
Overweight (BMI 25–30 kg/m ²)	1.13 (95% CI 0.87–1.46)
Obese (BMI >31 kg/m ²)	1.37 (95% CI 1.05–1.78)
Diabetes mellitus vs. none ¹⁹	HR 1.25 (95% CI 0.98–1.60)
Chronic obstructive pulmonary disease ²⁰⁹	RR:
FEV1 ≥80%	1.00 (reference)
FEV1 60%–80%	1.28 (95% CI 0.79–2.06)
FEV1 <60%	2.53 (95% CI 1.45–4.42)
Obstructive sleep apnea vs. none ²¹⁰	HR 2.18 (95% CI 1.34–3.54)
Chronic kidney disease ²¹¹	OR:
None	1.00 (reference)
Stage 1 or 2	2.67 (95% CI 2.04–3.48)
Stage 3	1.68 (95% CI 1.26–2.24)
Stage 4 or 5	3.52 (95% CI 1.73–7.15)
Smoking ²¹²	HR:
Never	1.00 (reference)
Former	1.32 (95% CI 1.10–1.57)
Current	2.05 (95% CI 1.71–2.47)
Alcohol consumption ²¹³	RR:
None	1.00 (reference)
1–6 drinks/wk	1.01 (95% CI 0.94–1.09)
7–14 drinks/wk	1.07 (95% CI 0.98–1.17)
15–21 drinks/wk	1.14 (95% CI 1.01–1.28)
>21 drinks/wk	1.39 (95% CI 1.22–1.58)
Habitual vigorous exercise ²¹	RR:

AF, Atrial fibrillation; BMI, body mass index; CI, confidence interval; FEV1, forced expiratory volume in 1 second; HR, hazard ratio; OR, odds ratio; RR, risk ratio.

From Kirchhof P, Benussi S, Kotecha D, et al. 2016 ESC guidelines for the management of atrial fibrillation developed in collaboration with EACTS. *Eur Heart J*. 2016;37:2893–2962.

Genetics. More than 5% of all patients with AF and 15% to 20% of those with AF in the absence of known causal conditions had a positive family history. Offspring of parents with AF (especially those with early-onset AF with no conventional risk factors) have a two- to threefold greater risk of developing AF. Several genes and genomic regions linked to AF and its substrate have been identified in families, individuals, and different populations. However, whether genetic profiles can be constructed to identify at-risk populations and whether intervention on modifiable risk factors can reduce the risk of AF in populations with genetic predisposition remain to be investigated.^{9,44,60}

Modifiable Risk Factors

Hypertension. Hypertensive heart disease is the most common underlying chronic disorder in patients with AF in developed countries. In fact, hypertension has been found to affect 49% to 90% of the participants in major AF clinical trials. Hypertension per se increases the risk of incident AF by about twofold. Furthermore, the coexistence of hypertension and AF increase the risk of stroke, heart failure, hospitalization, and overall mortality by twofold as compared to AF patients without hypertension. Longstanding hypertension, especially if suboptimally controlled, is associated with sympathetic activation, activation of the renin–angiotensin–aldosterone system, LV hypertrophy, diastolic dysfunction, LA stretch, and structural atrial remodeling, all of which can contribute to development and progression of AF. In addition, hypertension commonly coexists with multiple morbidities that also increase the risk of AF, such as heart failure, coronary artery disease, diabetes, and obesity.⁶¹

Of note, longitudinal patterns or long-term trajectories of systolic blood pressure, pulse pressure, and hypertension treatment were associated with higher 15-year risk of AF development, and performed better than single time-point measurements, especially where prolonged hypertension is present and antihypertensive treatment is used. Interestingly, distinct trajectories for diastolic blood pressure were not associated with increased 15-year risk of AF.⁵⁸

Heart failure. Heart failure and AF share several risk factors and common pathophysiologic processes. In a global AF registry, heart failure was prevalent in 33% of paroxysmal, 44% of persistent, and 56% of permanent AF patients. In the Framingham study, 41% of patients with AF and heart failure developed heart failure first, 38% developed AF first, and in the remaining 21% AF and heart failure occurred at the same time. On the other hand, AF develops in up to 42% of heart failure patients. The prevalence of AF increases with heart failure severity, ranging from 5% in functional class I patients compared with approximately 50% in class IV patients. Among a cohort of heart failure patients with preserved left ventricular ejection fraction (LVEF), 29% had a history of AF, and AF or AFL was documented in 65% of those presenting with acute diastolic heart failure.^{62,63}

Patients with concomitant heart failure and AF exhibit a grim prognosis, with a 1-year mortality of 9.5% and worsening of heart failure in almost 25%. In heart failure patients undergoing implantable cardioverter-defibrillator (ICD) implantation, a history of AF at time of procedure identifies additional risk of heart failure and death, and the new detection of AF afterward is associated with even higher rates of death.^{63,64}

In addition to their shared underlying risk factors, AF and heart failure also are independent risk factors for one another. AF can be both a cause and a consequence of heart failure. Heart failure is a potent risk factor for incident AF, with a sixfold increase in the risk of developing AF, while AF is associated with a threefold increased risk of incident heart failure. AF can cause impairment of systolic and diastolic ventricular function not present in sinus rhythm. The loss of atrial systole as well as AF-induced impaired atrial function and atrial fibrosis result

in reduced LV filling and cardiac output and can be a direct cause of diastolic heart failure. In addition, irregular and rapid ventricular rates in AF can lead to LV systolic dysfunction (tachycardia-induced cardiomyopathy). AF is also associated with LV myocardial fibrosis, which contributes to diastolic dysfunction. On the other hand, increased ventricular filling pressures and afterload, functional valvular regurgitation, and activation of the renin–angiotensin–aldosterone system in heart failure can lead to atrial stretch, fibrosis, and dilation. In addition, altered calcium handling and calcium overload in heart failure can promote initiation and perpetuation of AF.^{63–65}

Valvular heart disease. AF has been conventionally classified into “valvular” or “nonvalvular” AF. While the 2012 ESC Guidelines defined valvular AF as rheumatic valvular disease (predominantly mitral stenosis) or prosthetic heart valves, the 2014 AHA/ACC/HRS guidelines defined nonvalvular AF as AF in the absence of rheumatic mitral stenosis, or a mechanical heart valve, but explicitly added bioprosthetic heart valves or mitral valve repair.³

A wide spectrum of valvular lesions can lead to the development of AF. The major independent risk factor is LA enlargement, which is more likely to result from mitral valve disease. Elevated LA pressure causes myocardial stretch and atrial remodeling, which promote AF.

Rheumatic heart disease, now uncommon in developed countries, remains an important underlying substrate for AF in the developing world. The prevalence of AF in these patients varies with the type of valve disease, occurring in only 1% of patients with aortic valvular disease, 16% of those with isolated mitral regurgitation, 29% of patients with isolated mitral stenosis, and 52% of those with combined mitral stenosis and regurgitation. In addition, the risk of AF is known to correlate with LA size; the incidence of AF rises from 3% when the LA diameter is less than 40 mm to 54% if the LA diameter exceeds 40 mm. Patients with mitral stenosis and AF are at a particularly high risk for thromboembolic events and have been excluded from any further trials studying anticoagulation regimens for AF. The risk of thromboembolism is higher for AF patients with mitral than those with aortic valve disease.

Nonrheumatic valvular heart disease is common in patients with “nonvalvular” AF (i.e., valve disease with neither rheumatic mitral stenosis nor valve prosthesis), with reported prevalence of up to 25%, especially those with permanent AF. The majority of these patients have mitral regurgitation (61%), aortic regurgitation (24%), and aortic stenosis (32%). Of note, an increased thromboembolic risk has been observed in nonvalvular AF patients who have nonrheumatic native valve disease compared with those without valve disease; however, neither the valve disease per se nor its severity was clearly associated with this risk. Those patients were older and had a higher CHA₂DS₂-VASc score, which was likely to explain the higher embolic risk.³

Coronary artery disease. Coronary artery disease is present in more than 20% of patients with AF. In contrast, the prevalence of AF in the total population with chronic stable coronary artery disease is relatively low. Nonetheless, AF occurs transiently in 6% to 22% of patients with acute coronary syndromes, and its occurrence in this setting is associated with increased short- and long-term morbidity and mortality. Ischemic heart disease can predispose to the development of AF by atrial stretch and dilation secondary to ischemia-related diastolic and systolic ventricular dysfunction as well as atrial ischemia.

Recent evidence suggests that AF patients are at substantially increased risk (by 47%) of incident MI compared with those without AF. The relative risk is particularly higher in patients free of coronary artery disease at baseline (by 71%), in those younger than 60 years, and in women. Several mechanisms have been proposed to account for the increased risk of MI in AF patients: (1) AF-induced prothrombotic

state caused by increased systemic platelet activation, thrombin generation, and endothelial dysfunction; (2) AF-mediated inflammation that can potentially promote plaque rupture and MI; (3) direct coronary thromboembolism from LAA clots; (4) demand ischemia related to fast ventricular rates during AF; and (5) presence of common risk factors that predispose to the development of both AF and coronary artery disease (e.g., diabetes, hypertension, advanced age).^{66–68}

Congenital heart disease. During long-term follow-up, AF develops in more than one-third of patients with congenital heart disease. AF is more common in patients with severe congenital defects, residual left-sided lesions, or unrepaired heart disease. AF is frequently associated with markers of left-sided heart disease (i.e., LV systolic dysfunction and LA dilation) and is most commonly seen in patients with congenital aortic stenosis, mitral valve disease, palliated single ventricles, unrepaired heart defects, or end-stage heart disease.⁶⁹ Compared to patients without congenital heart defects or with simple congenital heart defects, AF develops at a younger age in patients with complex congenital heart defects. AF is rarely seen in patients with atrial septal defects before the age of 40 years, but the incidence can approach 50% in unrepaired patients beyond 60 years of age.^{70–72}

Coexistence of episodes of AF and macroreentrant atrial tachycardia (MRAT) has been reported in a considerable number of patients (33%) with congenital heart disease. Regular ATs preceded development of AF in about two-thirds of patients. Approximately 30% of patients who have previously undergone successful catheter ablation for MRAT develop AF during long-term follow-up.^{70,73}

Obstructive sleep apnea. Accumulating evidence demonstrates an independent association between AF and obstructive sleep apnea. AF occurs in 5% of individuals with severe sleep apnea and only 1% of those without sleep apnea. The prevalence of at least moderate sleep apnea was reported in up to 32% of patients with AF and structurally normal hearts. Furthermore, cross-sectional studies demonstrated that patients with AF had a significantly higher risk of obstructive sleep apnea than matched controls (49% vs. 33%), and multivariate analysis demonstrated a strong independent association between sleep apnea and AF (odds ratio, 2.2). In addition, several prospective studies showed that obstructive sleep apnea predicts the occurrence of future AF. Untreated obstructive sleep apnea was associated with a remarkably high rate of AF recurrence at 1 year compared with patients with unknown sleep apnea status (83% vs. 53%). The risk of AF in patients with obstructive sleep apnea appears to increase linearly along with the severity of obstructive sleep apnea. In some patients with obstructive sleep apnea and paroxysmal AF, paroxysms of AF were found to be nocturnal and, at least in part, temporally related to respiratory obstructive events.^{61,74}

Obstructive sleep apnea can affect AF response to medical and catheter ablation therapies. Patients with obstructive sleep apnea can have 25% to 31% increased risk for AF recurrence after catheter ablation in comparison with patients with no sleep apnea. On the other hand, the use of continuous positive airway pressure (CPAP) therapy is associated with more than 40% relative risk reduction in AF recurrence in patients with obstructive sleep apnea, regardless of the AF treatment strategy (medical therapy or catheter ablation).^{75,76}

Several mechanisms are proposed by which obstructive sleep apnea increases the risk of AF. Repetitive forced inspiration against a collapsed upper airway during apneic episodes generates substantial shifts in intrathoracic pressure, with consequent increase of venous return, leading to increased RV preload and LV afterload. Pressure and volume overload causes stretch of the atria and PV ostia. Acute atrial stretch can shorten atrial refractoriness (possibly by opening of stretch-activated ion channels) and impair atrial conduction. Repeated atrial stretch can lead to structural atrial remodeling with dilation and fibrosis. In addition,

repetitive apneas and hypopneas are accompanied by intermittent hypoxemia and hypercapnia, which cause chemoreceptor-induced sympathetic activation and parasympathetic withdrawal. Sympathetic hyperactivity (which is further enhanced by recurrent arousal) results in peripheral vasoconstriction and systemic hypertension, as well as increased heart rate, and reduced heart rate variability. Also, intermittent hypoxia and postapneic reoxygenation induce oxidative stress and inflammatory processes contributing to LA remodeling and fibrosis. These mechanisms can act as both triggers and perpetrators of AF, and can predispose to arrhythmia recurrence and affect response to different pharmacologic and nonpharmacologic therapies for AF. CPAP therapy is likely to effectively reverse these mechanisms and thereby decrease AF occurrence. Finally, obstructive sleep apnea often coexists with multiple morbidities that also increase the risk of AF, such as heart failure, diabetes, obesity, and systemic hypertension.^{74–76}

Obesity. Obesity (body mass index [BMI] greater than 30 kg/m²) is associated with a significantly higher risk of AF. Overweight populations have higher incidence, prevalence, severity, and progression of AF compared with their normal weight counterparts. A recent meta-analysis found that for every 5 kg/m² increase in BMI, there were 10% to 29% greater risks of incident, postoperative, and postablation AF.^{77,78} In overweight and obese individuals with symptomatic AF, progressive long-term sustained weight loss has a dose-dependent effect on long-term freedom from AF. Notably, weight fluctuation of greater than 5% had an adverse effect on overall freedom from AF, with a twofold greater likelihood of recurrent arrhythmia.^{44,61,79} A recent meta-analysis found a 3.1% greater risk of recurrent AF postablation for every one unit increase in BMI.

Obesity is often associated with cardiometabolic comorbidities, such as hypertension, diabetes mellitus, autonomic dysfunction, and sleep apnea, all of which can generate a susceptible AF substrate. However, obesity also appears to be a distinct risk factor for AF, independent of the coincidental accumulation of other comorbidities. Obesity was linked to higher risk of AF even among young and seemingly healthy individuals. Several mechanisms have been proposed to explain the association between obesity and AF. Progressive weight gain results in electrical and structural atrial remodeling, atrial interstitial fibrosis, increased LA pressure and volume, ventricular hypertrophy and impaired diastolic function, low-grade systemic inflammation, and myocardial lipidosis. Obesity has also been associated with increased epicardial fat thickness, which has been associated with AF, likely due to altered atrial electrophysiology and autonomic imbalance. On the other hand, weight loss is associated with reversal of atrial dilation and LV hypertrophy.^{79–81}

Diabetes. Diabetes appears to confer an increased risk for the development of AF. In the FHS, diabetes was associated with 40% higher risk of AF in men and 60% higher risk in women after 38 years of follow-up. Other studies found that AF was more prevalent in subjects with pre-diabetes compared to controls and correlated positively with hemoglobin A1c. Notably, intensive glycemic control does not affect the rate of new-onset AF.^{44,82,83}

Several mechanisms can potentially underlie the association of diabetes and AF. Diabetes-related cardiomyopathy leads to ventricular systolic or diastolic dysfunction, increased filling pressures, and atrial remodeling. In addition, cardiac autonomic neuropathy has been implicated by leading to sympathetic overactivity and neural remodeling. Furthermore, insulin resistance can be associated with a proinflammatory environment within the myocardium.^{82,83}

Hyperthyroidism. The prevalence of AF in patients with overt hyperthyroidism ranges between 10% and 15%, and the risk is approximately sixfold that of the euthyroid population. Also, subclinical hyperthyroidism is a risk factor associated with a threefold increase in

development of AF. The risk of AF is higher in men, in the elderly, and in patients with triiodothyronine (T3) toxicosis.^{44,84}

About two-thirds of the patients with AF due to hyperthyroidism revert spontaneously to NSR after treatment of the thyrotoxic state, typically within 3 to 6 months of becoming euthyroid. Even though hyperthyroidism is considered a reversible cause of AF, the arrhythmia persists or recurs in up to 30% to 40% of patients after restoring a euthyroid status. Older age (greater than 55 years), long duration of hyperthyroidism (greater than 5 years), long duration of pretreatment AF, severe LV dysfunction, and LA enlargement are independent predictors for continued AF following the successful treatment of hyperthyroidism.^{44,84}

Among all patients with new-onset AF, less than 1% of AF incidence is caused by overt hyperthyroidism. Although the yield of abnormal thyroid function testing in these patients is low, the benefit associated with the ability to restore patients with thyrotoxicosis to a euthyroid state and NSR justifies thyroid-stimulating hormone (TSH) testing in most patients with recent onset of otherwise unexplained AF.

The mechanisms by which hyperthyroidism enhances vulnerability to AF likely include abbreviation of the atrial action potential duration and refractory period, increased atrial ectopic activity, elevation of LA pressure secondary to increased LV mass and impaired ventricular relaxation, and myocardial ischemia resulting from increased resting heart rate.^{44,84}

Pulmonary embolism. AF can occur in the setting of acute pulmonary embolism, likely secondary to acute RV pressure overload and subsequent RA dilation. AF can be seen as a presenting sign, during the early phase, or later in the course of recovery from pulmonary embolism.⁸⁵ Furthermore, patients with prior pulmonary embolism exhibit a substantially increased (ninefold) incidence of late onset AF.⁸⁶

Of note, some studies have suggested that AF can potentially be a cause, rather than a consequence, of pulmonary embolism. The prothrombotic state associated with AF can potentially promote RA thrombus formation with subsequent embolization to the lungs. However, this hypothesis has yet to be confirmed.⁸⁶

Chronic kidney disease. Chronic kidney disease (CKD) increases the risk of the development of AF. Among patients with chronic kidney disease, the prevalence of AF is two- to threefold higher than reported in the general population. Moreover, AF prevalence increases in a dose-dependent fashion as renal function worsens. In one report, the prevalence of AF was 1.0% among adults without CKD, and 2.8%, 2.7%, and 4.2% among adults with stage 1 to 2, stage 3, and stage 4 t–5 CKD, respectively. Other measures of kidney dysfunction, such as albuminuria, are also associated with higher AF risk. Importantly, incident AF is independently associated with increased risk of progression to end-stage renal disease requiring dialysis in adults with chronic kidney disease (likely due to the proinflammatory, profibrotic, and prothrombotic state as well as altered hemodynamics associated with AF).

Several possible mechanisms can potentially explain the high rate of identified AF among patients with chronic kidney disease, including a high prevalence of shared risk factors between chronic kidney disease and AF (e.g., advanced age, LV hypertrophy, hypertension, diabetes), increased systemic inflammation, sympathetic activation, myocardial fibrosis, and activation of the renin–angiotensin–aldosterone system.

Exercise and fitness. Recent data describing the intensity, duration, and frequency of exercise suggest a U-shaped relationship with AF and mortality. Sedentary lifestyle significantly increases the risk of AF, while moderate-intensity exercise is protective against future AF in both men and women. However, vigorous long-term exercise training has a gender-specific association with AF risk. Compared with sedentary counterparts, men who exercised at a vigorous intensity had a threefold

risk of incident AF. In contrast, women exercising at vigorous intensities actually had a lower incidence of AF.^{61,87,88}

The mechanisms of AF promotion by endurance exercise remain speculative. Proposed contributors include atrial stretch and dilatation, LV hypertrophy, chronic systemic inflammation, increased vagal tone, sinus node remodeling, anatomic adaptation, and illicit drugs. However, it remains unclear why intense physical activity increases the AF risk only in men and not in women. Of note, AF in athletes is less likely to be associated with the common risk factors for AF identified in the general population.^{87,88} On the other hand, physical inactivity predisposes to AF risk factors (e.g., hypertension, obesity, and diabetes), and is associated with systemic inflammation and sympathetic activation.⁹

Alcohol. AF is the most common arrhythmia associated with alcohol consumption. Importantly, the total amount and pattern of alcohol drinking as well as the type of alcoholic beverage appear to impact AF risk. Habitual moderate (7 to 21 standard drinks/wk) and heavy (greater than 21 standard drinks/wk) alcohol consumption, even after correcting for binge drinking, increases the incidence of AF in a dose-dependent manner, with an 8% increase in AF risk for each 1 standard drink per day (or 12 g pure alcohol per day) increase of alcohol consumption.

In addition, an association exists between binge-pattern drinking (greater than 5 drinks on a single occasion) and increased AF risk, independent of the number of drinks consumed per week. AF in the setting of acute consumption is well recognized, occurring in up to 60% of binge drinkers. In fact, the “holiday heart syndrome” describes AF occurring following weekends or holidays when alcohol intake is increased. Furthermore, the risk for AF was found to be most pronounced with liquor, modest for wine, and no excess risk was detected with beer.^{44,89}

Among patients with a history of AF, alcohol consumption is associated with an increased risk of progression from paroxysmal to persistent AF as well as increased risk of AF recurrence following catheter ablation. A safe level of daily alcohol consumption in AF patients has not been identified.⁹⁰

Several mechanisms have been implicated in mediating the adverse effects of alcohol. Ethanol can lead to electrical atrial remodeling, resulting in slowing of intraatrial conduction and abbreviation of atrial refractoriness. Other potential mechanisms include sympathetic stimulation, modulation of vagal tone, alterations in oxidative stress, electrolyte imbalances (hypokalemia, hypomagnesemia), and alcohol-induced cardiomyopathy. Furthermore, ethanol and its metabolite, acetaldehyde, have direct cardiotoxic effects, including direct effects on atrial excitation-contraction coupling, inhibition of calcium release from the sarcoplasmic reticulum, generation of oxidative stress, accelerated protein catabolism, and derangements in fatty acid metabolism and transport.^{44,89,91,92}

Smoking. Several, but not all, studies demonstrated an association between past and current cigarette smoking and an increased risk of AF. In one report, current smokers exhibited almost twice the risk of AF as compared to never smokers. Past smokers also had an increased risk of AF, albeit lower than those who continued to smoke. Furthermore, the cumulative amount of smoking in cigarette-years was correlated with an increased risk of developing AF. In addition, second-hand smoking, particularly when present during development and early childhood, was statistically significantly associated with the presence of AF. This relationship was particularly strong in the absence of known AF risk factors. Of note, smoking has also been reported to predict worse outcome (i.e., increased risk of intracranial bleeding, mortality, and the combined outcome of stroke or death) in patients with AF.^{44,93}

Several mechanisms can be involved in the associations of smoking with AF. Nicotine itself has been linked to cardiac arrhythmias, including AF, likely secondary to sympathetic activation, atrial electrical alterations, atrial fibrosis, and atrial structural remodeling. Furthermore, carbon monoxide can influence cardiac automaticity. In addition, oxidant substances and polycyclic aromatic hydrocarbons can potentially play a role.⁹³

Caffeine. Caffeine, a methylxanthine compound that is chemically similar to theophylline, increases neurohormonal and sympathetic stimulation. Therefore caffeine has been addressed as a potential trigger for AF. However, studies failed to demonstrate any significant relationship between habitual or heavy caffeine consumption and incident AF.⁴⁴

Recreational drugs. Data on recreational (illicit) drugs as risk factors for AF per se are sparse. AF has not been reported to be associated with amphetamine, heroin, or LSD abuse. Limited reports suggest a potential effect of the abuse of cannabis, cocaine, ecstasy, and anabolic androgenic steroids on AF.⁴⁴

Cannabis, the most commonly used recreational drug, has been associated with several cases of AF (starting within minutes to 3 hours of cannabis use) in young people without comorbidities. The underlying mechanism probably is related to sympathetic activation and reduced coronary microcirculation.⁹⁴

Drug-Induced Atrial Fibrillation

Several cardiovascular and noncardiovascular drugs can induce AF. The overall incidence of drug-induced AF is relatively low; however, since drug-induced AF in most cases is paroxysmal, spontaneously terminating in a few minutes or hours, the true incidence of drug-induced AF is probably underestimated.

Transient AF is observed in approximately 3% of patients receiving adenosine for treating SVT and up to 17% of those receiving adenosine during EP studies. Also, AF can be induced by positive inotropic agents such as dobutamine for stress echocardiography (0.4% to 2%) and milrinone (5%). Furthermore, the use of dopamine, or dobutamine following cardiac surgery is associated with a higher incidence of postoperative AF. Paroxysmal AF is a relatively common complication (17%) following intracoronary injection of acetylcholine for the provocation of coronary spastic angina.

Several antineoplastic agents can induce AF, including intrapericardial cisplatin (12% to 32%), cyclophosphamide (2%), anthracyclines (1% to 10%), IL-2 (4% to 8%), melphalan (6% to 12%), 5-fluorouracil (1%), and paclitaxel (1% to 1.7%). Other drugs reportedly implicated in precipitating AF include nonsteroidal antiinflammatory agents, high-dose corticosteroids, ondansetron (an antiemetic agent), aminophylline, theophylline, antipsychotic agents (e.g., clozapine, olanzapine), antidepressants (e.g., fluoxetine, trazodone), bisphosphonates (e.g., alendronate), and ivabradine.

Several classes of drugs can induce AF through very different mechanisms, including: (1) alteration of atrial EP properties, with increased focal activity, shortened action potential duration and refractoriness, or reduced conduction velocity (e.g., adenosine, parasympathomimetics, sympathomimetics, and theophylline); (2) adrenergic or vagal stimulation (e.g., acetylcholine, adenosine, sympathomimetics); (3) direct cardiotoxicity causing myocardial fibrosis, cardiomyopathy, myocarditis, or pericarditis (e.g., cancer chemotherapy); (4) myocardial ischemia secondary to coronary vasospasm, thrombosis, or arteritis (e.g., acetylcholine, chemotherapy agents, ondansetron, and sumatriptan); (5) electrolyte disturbances (e.g., diuretics, glucocorticoids); (6) abnormalities in calcium handling (e.g., inotropic agents); (7) release of proinflammatory cytokines (e.g., IL-2); and (8) increased oxidative stress (e.g., cancer chemotherapy).^{44,94}

Postoperative Atrial Fibrillation

Epidemiology

Postoperative AF complicates cardiac surgery in 15% to 63% of patients. The risk of AF is highest among patients undergoing combined coronary artery bypass grafting and mitral valve replacement (63%) and the lowest among patients undergoing isolated coronary revascularization surgery (15% to 40%) and cardiac transplantation (11% to 24%). Postoperative AF has also been known to complicate noncardiac surgery (incidence, 0.3% to 13.7%), especially thoracic and large colorectal surgeries.⁹⁵

Clinical risk factors for the development of postoperative AF include advanced age (greater than 65 years), male gender, Caucasian race, hypertension, prior AF, mitral valve disease, heart failure, LV hypertrophy, diastolic dysfunction, increased LA size, history of MI, withdrawal of beta-blocker therapy, obesity, low BMI, chronic obstructive pulmonary disease, anemia, prolonged PR interval, diabetes, renal dysfunction, tobacco use, and high baseline CRP levels. The CHADS2 and CHA2DS2-VASc scores were also found to be predictive of AF after cardiac surgery.⁹⁶

Several factors related to the surgical procedure also potentially contribute to the development of AF. These include operative trauma from surgical dissection and manipulation, pericardial lesions, atrial dilation (caused by LV dysfunction and intraoperative volume overload), perioperative use of catecholamines, parasympathetic activation, and electrolyte imbalances.⁹⁷

The onset of postoperative AF peaks at 24 to 72 hours after surgery, and declines to 2% at discharge. Among patients with no prior history of AF, postoperative is usually self-limited, terminating within 24 hours in the majority of patients, with a mean duration of about 11 to 12 hours. However, despite its usually transient nature, the arrhythmia is not limited to the early postoperative phase, and can recur between day 6 and day 30 after the operation in about 25% of patients.^{96,97}

Prognosis

The occurrence of postoperative AF is associated with a twofold increase in cardiovascular mortality and morbidity. Postoperative AF is associated with a two- to fourfold increase in stroke risk at 30 days, and is an important predictor of in-hospital and long-term mortality. Numerous postoperative complications have been correlated with postoperative AF, including congestive heart failure, stroke, bleeding complications (from anticoagulation), renal insufficiency, infection, ventricular arrhythmias, prolonged ventilation, reintubation, readmission to the intensive care unit, and prolongation of hospital stay (by about 4 to 5 days). However, it is important to note that a causal relationship between postoperative AF and its associated adverse outcomes is still not well defined.⁹⁷⁻⁹⁹

Mechanism

Although the exact pathophysiology of postoperative AF remains incompletely understood, both acute perioperative and chronic factors appear to play an important role in the initiation and maintenance of the arrhythmia. Acute perioperative factors that have been implicated in the creation of atrial susceptibility to AF include pericardial inflammation, heightened sympathetic tone, use of inotropes, acute atrial injury, ischemia, and oxidative stress, as well as acute atrial dilation secondary to pressure or volume overload. Also, it is likely that a preexisting atrial electrical and structural arrhythmogenic substrate increases the vulnerability to the development of AF when subjected to the acute perioperative stress. In fact, the majority of patients with postoperative AF have underlying atrial disease. Further, the presence of preexistent atrial

substrate likely explains the increased risk for developing future AF among patients with new-onset postoperative AF, suggesting that the development of postoperative AF can be a surrogate for an underlying cardiac substrate.^{95,97}

CLINICAL PRESENTATION

Symptomatic Atrial Fibrillation

AF can be symptomatic or asymptomatic, even in the same patient. Symptoms associated with AF vary, depending on the ventricular rate, the underlying functional status, the duration of AF, the presence and severity of structural heart disease, and the individual patient's perception.

The hemodynamic consequences of AF are related to loss of coordinated atrial contraction, rapid ventricular rate, and irregularity of ventricular rhythm (independent of rate), as well as long-term consequences such as atrial and ventricular cardiomyopathy. Loss of effective atrial contraction can potentially reduce cardiac output by 15% to 25%. These consequences are magnified in the presence of impaired diastolic ventricular filling, hypertension, mitral stenosis, LV hypertrophy, and restrictive cardiomyopathy. Irregularity of the cardiac cycle, especially when accompanied by short coupling intervals, and rapid heart rates in AF can lead to reduction in diastolic filling, stroke volume, and cardiac output.^{100,101}

Most patients with AF complain of palpitations, chest discomfort, dyspnea, generalized fatigue, or dizziness, although significant interindividual and intraindividual variability exists. Although palpitation, or awareness of the irregularity of the heartbeat, is prominent in more than half of patients with AF (more common in those with paroxysmal AF), its correlation with documented arrhythmia is unimpressive. Dyspnea and fatigue can result in significant activity intolerance.

Chest pain can be related to demand ischemia secondary to reduced cardiac output during AF in patients with coronary artery disease; however, chest pain can occur in AF patients despite the absence of coronary artery disease, potentially related to impaired microvascular flow. Furthermore, AF with a chronically rapid heart rate (more than 120 to 130 beats/min) can lead to tachycardia-mediated cardiomyopathy and heart failure.

Syncope is an uncommon complication of AF that can occur on termination of the arrhythmia in patients with SND or (especially at the onset of an episode) because of rapid ventricular rates in patients with hypertrophic cardiomyopathy, aortic stenosis, or ventricular pre-excitation over a BT. The first presentation of asymptomatic AF can be catastrophic—an embolic complication or acute decompensation of heart failure.¹⁰²

AF is associated with two- to three-times higher risk of cognitive decline and all forms of dementia, including Alzheimer's disease, senile dementia, and vascular dementia. Potential mechanisms of dementia in AF patients include embolic or hemorrhagic strokes, altered cerebral blood flow in AF, and cerebral micro-bleeds from anticoagulation, oxidative stress, and proinflammatory or prothrombotic status.⁵⁵

In some patients, paroxysmal AF can be classified as either *vagal* or *adrenergic*, depending on the types of triggers and the temporal distribution of the arrhythmic episodes. Vagal AF typically occurs in young male patients without structural heart disease and characteristically develops during sleep or postprandial. In contrast, patients with adrenergic AF are usually older, often with evidence of underlying heart disease, and AF episodes usually occur during the day and are associated with physical or emotional stress. In patients with paroxysmal AF, the prevalence of vagal AF probably ranges between 6% and 25%, whereas that of adrenergic AF ranges between 7% and 16%. Pure adrenergic

and vagotonic forms of paroxysmal AF are uncommon. Approximately 12% of patients with paroxysmal AF exhibit features of mixed vagal and adrenergic patterns.

It is important to note that many patients with AF do not complain of palpitations and present primarily with occult cardiac symptoms, such as fatigue and effort intolerance. Such complaints should not be dismissed as “unrelated,” and those patients should not be labeled “asymptomatic.” On the other hand, many patients with persistent or permanent AF have one or more comorbid conditions (such as sleep apnea, heart failure, pulmonary disease) that can considerably contribute to specific complaints and to overall quality of life. Therefore it is imperative to establish a correlation between any symptoms and AF, as well as ventricular response rates. The effect of regulation of ventricular rate during persistent AF or conversion to NSR on a patient’s symptoms and quality of life can help assess the relative contribution of AF to the patient’s complaints. This is particularly important when the impact of AF on patient’s symptoms and quality of life is being considered as the indication for therapeutic interventions (such as ablation).

Atrial Fibrillation Symptom Scales

The Canadian Cardiovascular Society Severity in Atrial Fibrillation (CCS-SAF) scale (Table 15.3) and the modified European Heart Rhythm Association (EHRA) symptom scale (Table 15.4) have been developed to describe symptom severity and assess the functional consequences of symptoms in AF patients (analogous to the New York Heart Association [NYHA] congestive heart failure functional class and the CCS angina severity class). These scales can provide objective assessment of the patient’s subjective state, help guide symptom-orientated treatment decisions, and facilitate longitudinal patient profiling.

Silent Atrial Fibrillation

Asymptomatic, or silent, AF occurs frequently; approximately one-third of patients with AF and up to 65% of AF episodes have been shown to be asymptomatic. Furthermore, a poor correlation between symptoms and AF has been demonstrated, and perception of AF patients of their prevailing rhythm is often inaccurate. Continuous monitoring with a pacemaker with dedicated functions for AF detection showed that as many as 40% of patients experienced AF-like symptoms in the absence of AF, whereas 38% of patients with a history of AF had episodes of AF lasting more than 48 hours noted at the time of interrogation even though these patients were asymptomatic. Therefore the lack of symptoms should not be equated with the absence of AF, even in patients previously presented with symptomatic episodes of AF.^{100,101}

In individuals with no prior history of AF, silent AF can be noticed incidentally on routine physical examination or preoperative assessment, during active electrocardiographic screening in at-risk populations (e.g., patients with ischemic strokes), or in patients with cardiac implantable electronic devices (pacemakers, defibrillators, loop recorders). Furthermore, AF can be detected by new technologies, such as smartphone cases with ECG electrodes, smart watches, and blood pressure machines with AF detection algorithms. Occasionally, AF is discovered only after a complication attributable to AF (e.g., stroke or congestive heart failure). Up to 30% of patients presenting with cryptogenic strokes are found to have AF that was not previously recognized.^{55,103,104}

Asymptomatic AF, especially when paroxysmal, is often missed. It is estimated that 10% to 27% of all patients with AF remain undiagnosed due to the lack of symptoms. In the United States, the prevalence of undiagnosed AF is about 1% to 2% in the general population. Importantly, clinically silent AF is similar to symptomatic AF in terms of overall risks of death, cardiovascular death, or thromboembolic events.

TABLE 15.3 Canadian Cardiovascular Society Severity of Atrial Fibrillation Scale

Step 1: Symptoms

- Identify the presence of the following symptoms:
- Palpitation
- Dyspnea
- Dizziness, presyncope, or syncope
- Chest pain
- Weakness or fatigue

Step 2: Association

Is AF, when present, associated with the foregoing symptoms? For example: Ascertain whether any of the foregoing symptoms are present during AF and are likely caused by AF (as opposed to some other cause).

Step 3: Functionality

Determine whether the symptoms associated with AF (or the treatment of AF) affect the patient’s functionality (subjective QOL).

CCS-SAF Class Definitions

- | | |
|---------|--|
| Class 0 | Asymptomatic with respect to AF |
| Class 1 | Symptoms attributable to AF have minimal effect on patient’s general QOL <ul style="list-style-type: none"> • Minimal and/or infrequent symptoms, or • Single episode of AF without syncope or heart failure |
| Class 2 | Symptoms attributable to AF have minor effect on patient’s general QOL <ul style="list-style-type: none"> • Mild awareness of symptoms in patients with persistent or permanent AF, or • Rare episodes (e.g., less than a few per year) in patients with paroxysmal or intermittent AF |
| Class 3 | Symptoms attributable to AF have a moderate effect on patient’s general QOL <ul style="list-style-type: none"> • Moderate awareness of symptoms on most days in patient with persistent or permanent AF, or • More common episodes (e.g., more than every few months) or more severe symptoms, or both, in patients with paroxysmal or intermittent AF |
| Class 4 | Symptoms attributable to AF have a severe effect on patient’s general QOL <ul style="list-style-type: none"> • Very unpleasant symptoms in patients with persistent or paroxysmal AF and/or • Frequent and highly symptomatic episodes in patients with paroxysmal or intermittent AF, and/or • Syncope thought to result from AF, and/or • Congestive heart failure secondary to AF |

AF, Atrial fibrillation; CCS, Canadian Cardiovascular Society; QOL, quality of life; SAF, severity of atrial fibrillation.

From Dorian P, Guerra PG, Kerr CR, et al. Validation of a new simple scale to measure symptoms in atrial fibrillation: the Canadian Cardiovascular Society Severity in Atrial Fibrillation (CCS-SAF) scale. *Circ Arrhythm Electrophysiol*. 2009;2:268–275.

Device-Detected Atrial Fibrillation

Implanted pacemakers or defibrillators with atrial leads are capable of continuously monitoring the heart rhythm and detection of high atrial rates, providing a unique opportunity to identify the occurrence and burden of AF and correlating those episodes to patient’s symptoms (eFig. 15.4). The incidence of device-detected atrial high rate episodes varies depending on patient population, programmed device parameters

eFig. 15.4 Cardiac Device-Detected Atrial High Rate Episodes. Pacemaker interrogation strips from three different patients with dual-chamber pacemakers. (A) AF is present on the atrial (A) channel and correctly annotated on the marker (M) channel, with an atrial cycle length ranging between 140 and 190 milliseconds. Rapid and irregular ventricular response is observed on the ventricular (V) channel. (B) AF is present on the atrial channel, and the ventricular channel shows a well-controlled, irregular rhythm. On the marker channel, many of the low-amplitude atrial signals are under-sensed, leading to failure to detect atrial arrhythmias. (C) Sinus rhythm is present, but intermittent noise (high-frequency signals observed in the initial two-thirds of the recording) on the atrial channel is erroneously annotated on the marker channel as atrial activity, leading to inappropriate detection of atrial arrhythmias. AP, Atrial paced; AR, atrial-sensed event in the refractory period; AS, atrial sensed; FD, fibrillation detection; VP, ventricular paced; VS, ventricular sensed.

TABLE 15.4 The Modified European Heart Rhythm Association Symptom Scale

Modified EHRA Score	Symptoms	Description
1	None	AF does not cause any symptoms
2a	Mild	Normal daily activity not affected by symptoms related to AF
2b	Moderate	Normal daily activity not affected by symptoms related to AF, but patient troubled by symptoms ^a
3	Severe	Normal daily activity affected by symptoms related to AF
4	Disabling	Normal daily activity discontinued

^aEHRA class 2a and 2b can be differentiated by evaluating whether patients are functionally affected by their AF symptoms. AF-related symptoms are most commonly fatigue/tiredness and exertional shortness of breath, or less frequently palpitations and chest pain. AF, Atrial fibrillation; EHRA, European Heart Rhythm Association. From Kirchhof P, Benussi S, Kotecha D, et al. 2016 ESC guidelines for the management of atrial fibrillation developed in collaboration with EACTS. *Eur Heart J*. 2016;37:2893–2962.

(atrial rate and duration detection thresholds), and length of follow-up duration. In patients without prior history of AF, silent AF (as indicated by device-detected atrial high-rate episodes) is observed in nearly 30% of dual-chamber pacemaker recipients and 25% of cardiac resynchronization device recipients.^{103,105–107}

Accuracy of Device-Detected Atrial Fibrillation

Atrial high-rate episodes have been used as a surrogate for AF, and several studies have documented positive correlation between device-identified atrial high-rate episodes and ECG-documented episodes of AF or AFL with a high degree of sensitivity and specificity. However, different trials used different definitions of an atrial high-rate event (i.e., different programmed detection parameters of atrial rate and duration), and a clear consensus definition is still lacking. Nonetheless, employing an atrial rate cut-off of at least 220 beats/min (or greater than 250 beats/min for better specificity) sustained for durations exceeding 5 minutes provides good sensitivity and specificity for clinically confirmed AF (approaching 98% sensitivity and 100% specificity). Shorter cutoffs can lead to over-detection, commonly due to far-field R- and T-wave oversensing.¹⁰³

It is important to interpret device-stored data with caution. False-positive AF detection can result from oversensing (e.g., far-field R- and T-wave oversensing by the atrial lead, electrical interference, myopotentials, or repetitive nonreentrant ventriculoatrial synchrony) (see eFig. 15.4). On the other hand, under-detection of atrial activity is not uncommon due to the small amplitude of atrial electrograms during AF. In addition, atrial high-rate episodes are not specific for AF and can be triggered by AT and AFL. Inspection of device-stored electrograms (and not only marker channels) is important to verify the accuracy of the device diagnostics. However, because of the limited memory allocated for intracardiac electrograms, pacing devices may store only limited electrogram data to corroborate that the events labeled as atrial high-rate episodes or automatic mode switch events are indeed AF or AFL.^{106,107}

False-positive AF detection is also frequently encountered with implantable loop recorders with AF detection algorithms. False-positive detections are often caused by noise oversensing, frequent atrial or ventricular premature beats, T-wave oversensing, or sinus arrhythmia.

In one report, the accuracy of implantable loop recorders to detect true AF on a per patient basis was 96%; however, when the same analysis was performed on a per episode basis, then the overall accuracy of AF detection was only 48%.¹⁰⁷

Clinical Implications of Device-Detected Atrial Fibrillation

Several studies have clearly demonstrated that device-detected silent AFs are associated with increased risk of ischemic stroke and systemic embolism. The risk of thromboembolism appears to be related to the duration of AF episodes (or atrial high-rate episodes) as well as the patients' risk factor profile (CHA2DS2-VASc score).^{103,107}

The critical burden of atrial high-rate episodes beyond which thromboembolic risk is increased and that warrants therapeutic intervention remains to be defined. Several studies attempted to assess the burden of AF that is associated with adverse clinical outcomes, and AF burden thresholds ranging from 5 minutes to 24 hours were found in different reports to have clinical relevance. However, data are sparse on whether treatment with anticoagulation for subclinical device-detected atrial high-rate episodes reduces the risk of stroke to a similar degree as it does in clinical AF. In addition, current clinical practice guidelines for the treatment of device-detected atrial high-rate episodes are lacking. Based on current evidence, it seems appropriate to consider long-term oral anticoagulation for stroke prevention in high-risk patients with atrial high-rate episodes lasting longer than 5 to 6 minutes, when false-positive AF detections are excluded.^{103,106,107}

Of note, while device-detected silent AF is known to increase stroke risk, there does not seem to be a proximate temporal relationship between device-detected atrial high-rate episodes and the occurrence of strokes. In fact, in the majority of patients of a study population, no AF was detected on device recordings in the 30 days preceding the thromboembolic events. Although these data imply that the mechanism of stroke may not be related solely to the AF episodes, the association between the observation of atrial high-rate episodes and increased risk of stroke has been consistent, and silent AF is viewed as the culprit in cryptogenic stroke in these patients.¹⁰⁸ However, the value of continuous device-detected atrial arrhythmia information to guide therapeutic intervention for stroke prevention remains to be determined. A recent study suggested that a strategy of urgent initiation of anticoagulation based on device-detected AF did not improve outcomes, likely because of temporal dissociation between AF and stroke. Furthermore, withdrawal of anticoagulation in AF patients after arrhythmia-free periods on device interrogation was associated with worse outcome, implying that the decision on long-term anticoagulation in patients with AF should be based on more comprehensive, individualized assessment of risk and benefit rather than temporal incidence of arrhythmias detected by cardiac devices.¹⁰⁹

RISK OF THROMBOEMBOLISM

AF is a major risk factor for thromboembolism, causing approximately 15% of the ischemic strokes in the United States, 36% of strokes in patients older than 80 years, and up to 20% of cryptogenic strokes. Moreover, cardioembolic strokes caused by AF are large and multiple, often involve bilateral infarcts, and are associated with the highest rates of mortality and permanent disability. Specifically, patients with AF-related stroke show a 50% likelihood of death within 1 year, compared with 27% for strokes not related to AF.^{1,59}

In the FHS, patients with rheumatic heart disease and AF had a 17-fold increased risk of stroke compared with age-matched controls. For nonvalvular AF, the risk of stroke is estimated to be two to seven times that of subjects without arrhythmia, thus resulting in an average incidence of stroke of 5% per year. This rate may increase to 7% per

year when silent cerebral ischemic events and transient ischemic attacks are taken into account.

Although patients with AF in the setting of rheumatic valvular disease are expected to be at high risk of stroke, the stroke risk in nonvalvular AF is not homogeneous across the various subgroups of patients. The risk ranges from less than 1.5% per year in otherwise healthy AF patients who are less than 59 years old to more than 10% per year in older patients, especially when AF is associated with specific conditions or comorbidities. Prior history of stroke, transient ischemic attack, or thromboembolism, age, gender, ethnicity, hypertension, diabetes, coronary artery disease, peripheral artery disease, cardiomyopathy, and heart failure are important risk factors.¹¹⁰

Previous systematic reviews have not identified AF pattern (paroxysmal, persistent, or permanent) as an important prognostic risk factor for thromboembolism. In fact, AF stroke risk prediction models have in general not included AF type, and current clinical guidelines recommend that decisions regarding oral anticoagulation be made independently of AF pattern. However, recent data suggest that persistent and permanent AF is associated with an almost twofold higher rate of stroke or systemic embolism than paroxysmal AF after adjustment for other independent predictors.^{1,111–113}

In addition, a range of biomarkers have been identified as potential predictors of thromboembolic events in AF patients. These include markers of thrombosis (von Willebrand factor, D-dimer), myocardial necrosis (troponin), renal function (creatinine clearance, proteinuria), and the natriuretic peptides (N-terminal pro-B-type natriuretic peptide [NT-proBNP], BNP).

Severe findings on transesophageal echocardiography (TEE) have been identified as independent predictors of stroke and thromboembolism, including the presence of an LA thrombus (relative risk, 2.5), complex aortic plaques (relative risk, 2.1), spontaneous echo contrast (relative risk, 3.7), and low LAA velocities (up to 20 cm/s; relative risk, 1.7). Limited data suggest that large LAA dimensions on CMR may predict a higher risk of thromboembolism.

Stroke Risk Stratification

Several prominent risk stratification schemes have been developed to help distinguish patients with AF who are at high risk of ischemic stroke and other systemic thromboembolism from those with a risk sufficiently low that anticoagulation may not be beneficial when considering the associated bleeding risks.

The CHADS₂ index, named for a combination of clinical risk factors (Table 15.5), was the first risk stratification scheme to gain widespread acceptance due to its relative ease of use. The CHADS₂ system stratifies patients into low- (CHADS₂ score of 0), moderate- (score of 1 to 2), and high-risk (score of 3 to 6) categories. The stroke rate per 100 patient-years without antithrombotic therapy increases by a factor of approximately 1.5 for each one-point increase in the CHADS₂ score: from

1.9% for a score of 0 to 18.2% for a score of 6. A major limitation of the CHADS₂ scheme is the inadequate discrimination of risk. In fact, a large proportion (more than 60%) of patients are classified as having intermediate risk. Furthermore, this risk scheme is not adequately sensitive in identifying AF patients who are truly at low risk; many patients with AF categorized as low-risk by the CHADS₂ score still have stroke rates exceeding 1% per year.

Some of the limitations of the CHADS₂ scheme have been addressed by the newer CHA₂DS₂-VASc scoring system, which incorporates all components of the CHADS₂ system but with greater emphasis on age and includes two additional factors: female sex and vascular disease (Table 15.6). The CHA₂DS₂-VASc score has the major advantage of discriminating risk probability in lower risk patients and has been shown in multiple cohorts to be the best for identifying truly low-risk patients, even in those with a CHADS₂ score of 0 (Table 15.7). A low-risk score is defined as a CHA₂DS₂-VASc score of 0, an intermediate risk is defined as a score of 1, whereas a high-risk CHA₂DS₂-VASc score is defined by a score of 2 or greater.^{1,114}

The R2CHADS₂ risk model has emerged from an analysis of the ROCKET-AF (Rivaroxaban Once Daily Oral Direct Factor Xa Inhibition Compared with Vitamin K Antagonism for Prevention of Stroke and Embolism Trial in Atrial Fibrillation) population and was validated in an ATRIA (Anticoagulation and Risk Factors in Atrial Fibrillation) population. In addition to incorporating the same components of the CHADS₂ score, the R2CHADS₂ scheme awards 2 points for renal dysfunction.¹¹⁵

The ATRIA score contains elements of R2CHADS₂ but importantly gives different scores for age ranges that vary according to whether the patient had also suffered a stroke or transient ischemic attack (Table 15.8). In one report, the ATRIA score outperformed CHADS₂ and CHA₂DS₂-VASc risk scores largely because its use resulted in an appropriate downward classification (toward no risk).¹¹⁶

The ABC (age, biomarkers, clinical history) stroke risk score incorporates two biomarkers (NT-proBNP and high sensitivity cardiac troponin) and two clinical risk predictors (age and prior stroke) (Fig. 15.7).¹¹⁷

It is important to note that all current risk scores for the prediction of ischemic stroke in AF perform modestly. The ACC/AHA/HRS and ESC guidelines recommend the CHA₂DS₂-VASc score for stroke risk stratification in AF.¹¹⁶

Importantly, stroke risk assessment schemes have been established for patients with “nonvalvular” AF. Patients with mechanical valves require anticoagulation with vitamin K antagonists irrespective of the presence of AF. Also, AF patients with mitral stenosis are at a particularly

Fig. 15.7 The ABC (Age, Biomarkers, Clinical History) Stroke Risk Score. Nomogram for the ABC risk score. For each predictor, read the points assigned on the 0–10 scale at the top and then sum these points. Find the number on the “Total Points” scale and then read the corresponding predictions of 1- and 3-year risk of stroke or systemic embolism below it. Continuous variables are represented from the 1st to the 99th percentiles. The prediction model is preferably used as a web-based calculator or app. NT-proBNP, N-terminal pro-B-type natriuretic peptide; SE, systemic embolism; TIA, transient ischemic attack. (From Hijazi Z, Lindbäck J, Alexander JH, et al. The ABC (age, biomarkers, clinical history) stroke risk score: a biomarker-based risk score for predicting stroke in atrial fibrillation. *Eur Heart J*. 2016;37(20):1582–1590.)

high risk for systemic thromboembolism and have been excluded from any further trials studying anticoagulation regimens for AF. The 2014 AHA/ACC/HRS guidelines also include patients bioprosthetic heart valves or mitral valve repair in the definition of “valvular” AF.

On the other hand, stroke risk stratification using the above risk schemes appears to be adequate to guide treatment decisions regarding prophylactic anticoagulation therapy in patients with “nonvalvular” AF who have left valvular disease not included in the definition of “valvular” AF (e.g., nonrheumatic mitral regurgitation or aortic valve disease).^{3,4} In a recent report, left valvular disease was present in 22% of all non-valvular AF patients, and although the embolic risk is higher in these patients compared with those without valve disease, neither the valve disease per se nor its severity was clearly associated with this risk, and a higher CHA2DS2-VASc score in these patients was likely to explain these results.

Bleeding Risk Stratification

Oral anticoagulation is associated with increased risk of bleeding. It is estimated that up to 44% of patients with AF have one or more absolute or relative contraindications for long-term oral anticoagulation therapy, most commonly related to increased risk of bleeding. Therefore an assessment of bleeding risk should be part of the patient assessment before starting anticoagulation. The risk of bleeding should be weighed against the potential benefit of stroke prevention in individual patients considered for anticoagulation therapy.

Several risk models have been proposed to predict bleeding risk on antithrombotic therapy. Only the HAS-BLED (Table 15.9), HEMORR2HAGES (Table 15.10), ATRIA (Table 15.11), and ORBIT scores (Table 15.12) have been derived or validated in AF populations.¹¹⁸

TABLE 15.9 Clinical Characteristics Comprising the HAS-BLED Bleeding Risk Score

Letter	Clinical Characteristic	Points
H	Hypertension ^a	1
A	Abnormal liver or renal function	1 or 2
S	Stroke	1
B	Bleeding	1
L	Labile INR	1
E	Elderly (age >65)	1
D	Drugs or alcohol	1 or 2
Maximum score		9

^aHypertension is defined as systolic blood pressure >160 mm Hg. Abnormal kidney function is defined as the presence of long-term dialysis or renal transplantation or serum creatinine concentration of at least 200 μ mol/L. Abnormal liver function is defined as chronic hepatic disease (e.g., cirrhosis) or biochemical evidence of significant hepatic derangement (e.g., bilirubin more than twice the upper limit of normal, in association with aspartate aminotransferase, alanine aminotransferase, and alkaline phosphatase more than three times the upper limit of normal). Bleeding refers to previous bleeding history or predisposition to bleeding, or both (e.g., bleeding diathesis, anemia). Labile INRs refers to unstable or high INRs or poor time in therapeutic range (e.g., <60%). Drugs or alcohol use refers to concomitant use of drugs (e.g., antiplatelet agents, nonsteroidal antiinflammatory drugs, or alcohol abuse). INR, International normalized ratio.

eGFR, Estimated glomerular filtration rate.

In a study evaluating three bleeding risk scores (HAS-BLED, HEMORR2HAGES, and ATRIA), all three tested risk schemes demonstrated only modest performance in predicting the outcome of any clinically relevant bleeding, although the HAS-BLED score performed better than the HEMORR2HAGES and ATRIA scores; only HAS-BLED demonstrated a significant predictive performance for intracranial hemorrhage. Given its simplicity, the HAS-BLED score may be an attractive method for the estimation of oral anticoagulant-related bleeding risk for use in clinical practice, as recommended by the ESC guidelines. Patients are categorized as low, intermediate, and high bleeding risk according to HAS-BLED scores 0 to 1, 2, and 3 or higher, respectively. A score higher than 2 suggests a risk of major bleeding of 1.9% per year, whereas a score of 5 is associated with a risk of major bleeding of up to 12.5% per year.

It is important to understand that bleeding risk assessment is not a static phenomenon, and many common clinical factors that increase bleeding risk are potentially reversible. Further, a high bleeding risk score is not a reason to withhold anticoagulation therapy as such patients can potentially derive even greater net clinical benefit while on oral anticoagulation therapy. Instead, a high score should prompt careful review and follow-up as well as aggressive efforts at amelioration of potentially reversible bleeding risk factors (e.g., uncontrolled hypertension, labile international normalized ratios [INRs], balance problems, concomitant use of antiplatelet agents, alcohol excess, anemia, and renal or hepatic insufficiency).

INITIAL EVALUATION

The initial evaluation of a patient with suspected or documented AF includes characterizing the pattern of the arrhythmia (e.g., paroxysmal or persistent), determining underlying causes (e.g., heart failure, pulmonary problems, hypertension, hyperthyroidism), defining associated cardiac and extracardiac conditions, and identifying potential complications of AF. In addition, a thorough history should be obtained to estimate of the risk of stroke (using the CHA2DS2-VASc scheme), bleeding risk, and quantify AF-related symptoms (e.g., CCS-SAF and modified EHRA scores). A careful history results in a well-planned focused work-up that serves as an effective guide to therapy.

The physical examination can suggest AF based on irregular pulse, irregular jugular venous pulsations, and variation in the intensity of the first heart sound. Examination can also disclose associated valvular heart disease, myocardial abnormalities, or heart failure.

Diagnostic Cardiac Testing

Ambulatory cardiac monitoring can be required for documentation of AF, its relation to symptoms, and evaluation of the adequacy of heart rate control. Transthoracic echocardiography is performed to evaluate

for structural heart disease, assess cardiac function, and evaluate atrial size. Exercise testing is often used to assess the adequacy of rate control with exercise in permanent AF, to reproduce exercise-induced AF, and to evaluate for associated ischemic heart disease. Although ischemia per se does not appear to be a common cause of AF, identifying underlying coronary artery disease (in patients with risk factors) is particularly important if the use of a class IC antiarrhythmic drug is being considered.^{1,4,102}

Laboratory Testing

Laboratory evaluation includes assessment of serum electrolytes, renal, and hepatic function, and a blood count. Assessment for thyrotoxicosis is indicated for all patients with a first episode of AF, when the ventricular response to AF is difficult to control, or when AF recurs unexpectedly after cardioversion. Serum should be obtained for measurement of TSH and free thyroxine (T₄), even if there are no other symptoms suggestive of hyperthyroidism, because the risk of AF is increased even in patients with subclinical hyperthyroidism.⁴

Of note, plasma levels of B-type natriuretic peptide or N-terminal pro-B-type natriuretic peptide can be elevated in patients with paroxysmal and persistent AF in the absence of clinical heart failure, and levels decrease rapidly after restoration of sinus rhythm.⁴

Electrophysiological Testing

Rarely, EP testing can be required, especially in patients with wide QRS complex tachycardia or a possible predisposing arrhythmia, such as AFL or paroxysmal SVT. Clues to the presence of paroxysmal SVT include a history of episodes of regular rapid palpitations dating from teenage or early adult years (unusual for AF to occur de novo in this age group) and termination of episodes of palpitations with vagal maneuvers or adenosine (which should not occur with AF).

Other Diagnostic Tests

Other diagnostics as guided by clinical presentation may include chest radiography, pulmonary function tests, and sleep study.

Screening for Atrial Fibrillation

AF is an important cause of embolic stroke, and subclinical (silent) AF should be considered in all survivors of an ischemic stroke, especially those of undetermined source (i.e., cryptogenic stroke). Studies have demonstrated that AF can be detected on ambulatory cardiac monitoring in more than 6% of unselected stroke patients and in up to 30% of those with cryptogenic stroke, with the latter accounting for approximately one-third of all ischemic strokes. In a recent meta-analysis, the overall proportion of newly detected AF was 7.4%, but varied widely depending on the timing, duration, and method of cardiac monitoring. Extending continuous electrocardiographic monitoring from 24 hours to 30 and 180 days increased the detection of AF from 4.2% to 15.2% and 29.2%, respectively. Hence, long-term (greater than or equal to 30 days) continuous ECG monitoring (noninvasive or using an implantable loop recorder) is recommended after cryptogenic stroke, and probably is also reasonable in all survivors of an ischemic stroke, even when another competing cause for stroke has been identified clinically (e.g., hypertension or carotid artery stenosis).^{55,59,119}

Opportunistic screening for silent AF (pulse palpation during a general practitioner consultation for any reason, followed by an ECG if the pulse was irregular) may also be considered in at-risk populations (e.g., individuals older than 65 years and patients with heart failure).^{55,120}

Furthermore, patients with pacemakers or defibrillators should be followed periodically and their devices interrogated on a regular basis for any evidence of AF, as suggested by automatic mode switch or atrial high-rate episodes. Wireless remote monitoring with predefined auto-

matic alerts helps reduce the time to a clinical decision in response to the alert, compared with standard in-office follow-up.¹⁰⁶

PRINCIPLES OF MANAGEMENT

Management of AF should be aimed at identifying and treating underlying causes of the arrhythmia, as well as reducing symptoms, improving quality of life, and preventing cardiovascular morbidity and mortality associated with AF. There are four main issues that must be addressed in the treatment of AF: (1) prevention of systemic embolization; (2) ventricular rate control; (3) restoration and maintenance of NSR; and (4) risk factor modification.¹

The choice of therapy is influenced by patient preference, associated structural heart disease, severity of symptoms, and whether the AF is recurrent paroxysmal, recurrent persistent, or permanent. In addition, patient education is critical, given the potential morbidity associated with AF and its treatment. For control of symptoms, a safety-driven approach is of paramount importance because most treatments (drug, surgery, ablation) have the capacity to produce significant morbidity and even mortality.

Prevention of Systemic Embolization

Antithrombotic Drug Therapy

Antiplatelet therapy. Aspirin is associated with only modest (22%) reduction in the incidence of stroke, corresponding to an absolute stroke risk reduction of 1.5% per year as compared with placebo. Thus except in the lowest risk patients, aspirin alone is not a viable treatment option for stroke prevention. The combination of aspirin plus clopidogrel is superior to aspirin therapy alone (28% relative risk reduction), but it is associated with a significantly increased risk of major bleeding (2.0% vs. 1.3% per year) to levels generally similar to those associated with warfarin therapy.

Vitamin K antagonists. Vitamin K antagonists (warfarin) reduce stroke risk by approximately 64%, corresponding to an absolute annual strokes risk reduction of 2.7% as compared with placebo. Warfarin is superior to aspirin, with relative risk reduction of 39% for stroke and 29% for cardiovascular events. However, warfarin increases the risk of major bleeding by approximately 70% compared with aspirin. Although the risk of intracranial hemorrhage is doubled with adjusted-dose warfarin compared with aspirin, the absolute risk increase appears to be small (0.2% per year). In addition, randomized clinical trials have shown that warfarin is superior to the combination of aspirin plus clopidogrel for prevention of vascular events in patients with AF at high risk of stroke (relative risk reduction of 40%), with similar risks for major bleeding events. Combinations of warfarin (INR, 2.0 to 3.0) with antiplatelet therapy offer no incremental benefit in stroke risk reduction while they increase the risk of bleeding.

The reduction in ischemic stroke with warfarin in patients with paroxysmal AF is probably similar to that in patients with persistent or permanent AF. The benefit of warfarin is greatest for patients at higher risk of stroke, and there appears to be little benefit for those with no risk factors. The true efficacy of warfarin is likely to be even higher than suggested by trial results because many of the strokes in the warfarin-treated groups occurred in patients who were noncompliant at the time of the stroke.

The estimated annual incidence of bleeding associated with warfarin therapy is 0.6% for fatal bleeding, 3.0% for major bleeding, and 9.6% for major or minor bleeding. The risk of bleeding appears to be especially high during the first year of treatment. The addition of aspirin to warfarin further increases the rate of bleeding with a threefold increase in the rates of intracranial hemorrhage. Notably, the risk of major bleeding in older patients (greater than 80 years) receiving warfarin

therapy, although higher than younger patients, is acceptably low (2.5% per year), and these patients can still benefit from warfarin prophylaxis when a good quality of anticoagulation is obtained. The risk of falling and intracranial bleeding should be considered but not overstated.

An INR between 2.0 and 3.0 is recommended for most patients with AF who receive warfarin therapy. The risk of stroke doubles when the INR falls to 1.7, and values up to 3.5 do not confer an increased risk of bleeding complications. A higher goal (INR between 2.5 and 3.5) is reasonable for patients at particularly high risk for embolization (e.g., prior thromboembolism, rheumatic heart disease, prosthetic heart valves). Similarly, in patients who sustain ischemic stroke or systemic embolism during treatment with therapeutic doses of warfarin (INR, 2.0 to 3.0), raising the intensity of anticoagulation to a higher INR range of 3.0 to 3.5 should be considered. This approach is probably preferable to adding an antiplatelet agent because an appreciable risk in major bleeding is seen with warfarin only when the INR is greater than 3.5 and is likely to be less than that associated with combination therapy.

Warfarin therapy is associated with several limitations that have dampened the enthusiasm of both patients and clinicians: a narrow therapeutic window that requires periodic INR monitoring and frequent dose adjustments, multiple drug and dietary interactions, genetic variability in response (accounting for 39% to 56% of the variability in the warfarin dose), long half-life (36 to 42 hours), and slow onset of action. In several trials, more than one-third of the patients refused warfarin therapy, largely because of the lifestyle changes required, the inconvenience of INR monitoring, and concern about bleeding risk. These issues have contributed to the underutilization of anticoagulation therapy in patients who can stand to derive benefit from it. In fact, it is estimated that less than 50% of eligible patients were treated with warfarin. Of those patients prescribed warfarin, there is ongoing attrition of its use to approximately 40% by 4 years.

Several series have highlighted the difficulties of maintaining the INR in the therapeutic range. More than one-third of patients taking warfarin are not maintained in the therapeutic range, thus exposing them to increased risk of either stroke (with subtherapeutic INRs) or bleeding (with supratherapeutic INRs). It has been found that if a patient's INR is not maintained in the therapeutic range at least 65% of the time, the advantage of taking warfarin over aspirin is nullified.

Non-vitamin K antagonist oral anticoagulants. There are two classes of non-vitamin K antagonist oral anticoagulants (NOACs): factor Xa inhibitors (such as rivaroxaban, apixaban, and edoxaban), and direct thrombin inhibitors (dabigatran). In general, NOACs are at least as effective as warfarin for the prevention of stroke and systemic thromboembolism in patients with nonvalvular AF and are much safer regarding the risk of intracranial hemorrhage compared to warfarin, with the annual rate ranging from 0.23% to 0.50%. However, limited data exist concerning the potential advantage of using NOACs in patients taking warfarin with optimal INR control (time in therapeutic range more than 75%).

NOACs have several potential advantages over warfarin, including their rapid onset of action, predictable therapeutic effect, less complex pharmacodynamics, limited dietary and drug interactions, and stable dose-related coagulation profile allowing for fixed dosing and obviating the need for routine monitoring. These advantages will likely promote greater use of anticoagulants, enhance patients' compliance, allow for routine therapy without monitoring, and possibly eliminate the need for anticoagulation with parenteral agents such as heparin ("bridge therapy"). However, warfarin will remain the mainstay of treatment for patients with "valvular" AF and those with mechanical heart valves.

In a meta-analysis of trials randomizing NOACs to warfarin, NOACs were associated with: (1) significantly reduced composite stroke or

systemic embolic events (19%), primarily driven by a reduction in hemorrhagic stroke; (2) a nonsignificant (14%) reduction in major bleeding, a reflection of decreased intracranial hemorrhage; and (3) a significant reduction in all-cause mortality. Major bleeding rates with these agents exceeded 2% to 3% per year, and minor bleeding rates were over 10% per year. In addition, by 2 years, 21% to 33% of patients discontinued the NOAC.

There are no direct head-to-head trials comparing the NOACs. In a meta-analysis using adjusted indirect comparisons, there was significant heterogeneity in results. Dabigatran lowered the composite of systemic emboli or stroke (vs. rivaroxaban), and apixaban lowered the risk of major gastrointestinal bleeding (vs. both rivaroxaban and dabigatran). Currently, there is no clear evidence to support a possible class-effect of a direct thrombin inhibitor or factor Xa inhibitors.¹²¹

Nonpharmacological Interventions

The LAA has been implicated as the source of emboli in approximately 90% of patients with nonvalvular AF. Therefore several approaches have targeted exclusion of the LAA from the systemic circulation to prevent systemic thromboembolism and obviate the need for long-term oral anticoagulation therapy in patients with nonvalvular AF. These approaches can be of value in many AF patients, given the fact that up to 44% of patients with AF have one or more absolute or relative contraindications for chronic oral anticoagulation therapy, most commonly related to increased risk of bleeding. Furthermore, the safety and efficacy of chronic anticoagulation therapy can be limited by medication compliance, costs, and interactions with food and other medications.¹²²

Three main techniques are being utilized to accomplish LAA exclusion: percutaneous endocardial, percutaneous epicardial, and surgical approaches. Device-based endocardial LAA exclusion, such as Watchman (Boston Scientific, Natick, MA, United States) and Amplatzer Cardiac Plug (St. Jude Medical, Minneapolis, MN, United States), result in mechanical occlusion of the LAA. LAA exclusion with the endo-epicardial system (Lariat, SentreHEART, Redwood City, CA, United States) and surgical epicardial ligation result in both mechanical and electrical isolation of the LAA as a result of LAA infarction. Currently, these techniques are in different stages of evaluation and clinical development.

The ESC recommends percutaneous LAA closure device (Watchman and Amplatzer) use in nonvalvular AF patients with high stroke risk and contraindications to long-term oral anticoagulation. The 2014 AHA/ACC/HRS currently only recommends surgical excision of the LAA in patients undergoing cardiac surgery.

Potential candidates for percutaneous LAA closure include AF patients at high stroke risk with high risk of bleeding under oral anticoagulation, those with ischemic stroke despite well-controlled oral anticoagulation therapy, high probability of therapeutic noncompliance to oral anticoagulation, and intolerance to oral anticoagulation therapy due to severe hepatic or renal dysfunction or drug interactions (Box 15.1). The procedure is contraindicated in patients at low stroke risk, those with valvular AF (e.g., mitral stenosis, mechanical cardiac valves), in the presence of other indications for long-term or lifelong oral anticoagulation therapy (e.g., venous thromboembolism, intracardiac clots), LAA thrombus, and contraindications for transseptal catheterization (Box 15.2).

It is important to note that, although LAA exclusion procedures have been increasingly used for patients with nonvalvular AF, these procedures should not be considered universally as a substitute for oral anticoagulation therapy. Many of the disadvantages of warfarin therapy can be addressed by using NOACs rather than LAA exclusion, especially given the paucity of data supporting such procedures as compared to the large, prospective, randomized studies indicating the efficacy and safety of NOACs.

BOX 15.1 Possible Indications for Percutaneous Left Atrial Appendage Closure in Patients With Nonvalvular Atrial Fibrillation

- High stroke risk in conjunction to high bleeding risk under oral anticoagulation
- Ischemic stroke despite well-controlled oral anticoagulation therapy
- High probability of therapeutic noncompliance to oral anticoagulation
- Intolerance to oral anticoagulation therapy due to severe hepatic or renal dysfunction or drug interactions

BOX 15.2 Contraindications for Percutaneous LAA Closure in Patients With Nonvalvular AF

- Low stroke risk
- Valvular AF
- Presence of other indications for long-term oral anticoagulation
- LAA thrombus
- Contraindications for transseptal catheterization

AF, Atrial fibrillation; LAA, left atrial appendage.

Recommendations for Long-Term Stroke Prevention

The cornerstone of management of patients with AF is adequate thromboprophylaxis. Essential to this is appropriate risk stratification and the need to balance the benefit of stroke prevention and the risk of bleeding with anticoagulant therapies (see above). Decision making for thromboprophylaxis by antithrombotic therapy must balance the risk of stroke against the risk of major bleeding, especially intracranial hemorrhage, which is associated with a high risk of death and disability.

Patients with valvular AF (those with mitral stenosis or valvular prosthesis) should be managed with oral anticoagulation. For nonvalvular AF, the CHA₂DS₂-VASc scoring system (see Tables 15.6 and 15.7) is currently the best validated and most clinically useful for risk stratification and is advocated by both European and United States guidelines. The initial decision step is to identify patients who are truly at low risk for ischemic stroke, in whom no antithrombotic therapy is recommended. These include patients without clinical stroke risk factors (i.e., CHA₂DS₂-VASc score of 0 in men or 1 in women); female gender does not appear to increase stroke risk in the absence of other stroke risk factors. On the other hand, oral anticoagulation therapy is recommended for patients of both sexes with CHA₂DS₂-VASc stroke risk score greater than or equal to 2. Those recommendations apply to all patients with AF irrespective of the type of AF (paroxysmal or nonparoxysmal).

There is uncertainty regarding the optimal antithrombotic therapy in low thromboembolic risk patients (i.e., CHA₂DS₂-VASc score of 1 in men or 2 in women). According to the 2014 AHA/ACC/HRS guidelines, no antithrombotic therapy or treatment with an oral anticoagulant or aspirin can be considered in these patients. On the other hand, recent studies, as well as ESC guidelines, support a positive advantage for stroke prevention with oral anticoagulation compared with no therapy or with aspirin in these patients. Furthermore, the use of NOACs may lower the threshold for initiating anticoagulation for AF patients, given the positive net clinical benefit of NOACs, even in patients with a CHA₂DS₂-VASc score of 1.

Importantly, treatment decisions should be individualized. Careful assessment of the risk of bleeding and patient preference is crucial. The

TABLE 15.13 SAME-TT2R2 score

^bInteracting drugs, e.g., amiodarone for rhythm control.

expected clinical benefit of anticoagulation therapy should be balanced against the bleeding risk and should be thoroughly discussed with the informed patient. For equivocal cases, considering other possible risk predictors and risk models beyond the CHA₂DS₂-VASc scheme (e.g., renal function, biomarkers, findings on TEE) can potentially provide additional prognostic information and help identify those patients at a truly low thromboembolic risk.¹²³

The choice of anticoagulation therapy (warfarin vs. NOACs) is usually influenced by patient's preference, comorbidities, renal function, cost, and drug interactions. The use of SAME-TT2R2 score (Table 15.13) can potentially identify those patients in whom warfarin therapy is more likely to be associated with labile INRs and, consequently, serious bleeding and thromboembolism (SAME-TT2R2 score greater than 2). In those patients, NOACs are expected to offer a particular advantage.

In high-risk patients who cannot be treated with oral anticoagulation because of poor tolerance or noncompliance issues or because of strong patient preference, dual antiplatelet therapy (aspirin plus clopidogrel) can be considered. However, dual antiplatelet therapy is not an alternative to oral anticoagulation in patients at high bleeding risk because the risk of major bleeding associated with dual antiplatelet therapy is generally similar to that with oral anticoagulation. In the latter group, aspirin monotherapy is associated with lesser bleeding risk, although at the expense of less protection from systemic thromboembolism. Percutaneous LAA exclusion procedures have become an important therapeutic alternative to long-term antithrombotic therapy in these patients.

Anticoagulation in the Pericardioversion Period

Patients without a contraindication to oral anticoagulation who have been in AF for more than 48 hours should receive 3 to 4 weeks of oral anticoagulation with warfarin or NOACs (with documented therapeutic INRs for those on warfarin) prior to and after cardioversion. This approach is also recommended for patients with AF who have valvular disease, evidence of LV dysfunction, recent thromboembolism, or AF of unknown duration.

The rationale for anticoagulation prior to cardioversion is based on observational studies showing that more than 85% of LA thrombi resolve after 4 weeks of anticoagulation therapy. Cardioversion-related clinical thromboembolic events have been reported in 5% to 7% of patients who did not receive anticoagulation before cardioversion (this risk appears to be much lower [less than 1%] for AF of less than 48-hour duration).

An alternative approach that eliminates the need for prolonged anticoagulation prior to cardioversion, particularly in low-risk patients

who would benefit from earlier cardioversion, is the use of TEE-guided cardioversion. Cardioversion is performed if TEE excludes the presence of intracardiac clots. Anticoagulation after cardioversion, however, is still necessary.

After cardioversion, it is recommended to continue oral anticoagulation therapy for at least 4 weeks. This recommendation deals only with protection from embolic events related to the cardioversion period. Subsequently, the long-term recommendations for patients who have been cardioverted to NSR but are at high risk for thromboembolism are similar to those for patients with chronic AF, even though the patients are in NSR.

A different approach with respect to anticoagulation can be used in low-risk patients (with no mitral valve disease, severe LV dysfunction, or history of recent thromboembolism) in whom there is reasonable certainty that AF has been present for less than 48 hours. Such patients have a low risk of clinical thromboembolism (0.8% in one study) if converted early, even without surveillance TEE. The ACC/AHA guidelines do not recommend long-term anticoagulation prior to cardioversion in such patients, but they do recommend heparin use at presentation and during the pericardioversion period. The optimal therapy after cardioversion in this group is uncertain. A common practice is to administer aspirin for a first episode of AF that converts spontaneously and anticoagulation for at least 4 weeks in all other patients. Aspirin should not be considered for patients with AF of less than 48 hours' duration if there is associated rheumatic mitral valve disease, severe LV dysfunction, or recent thromboembolism. Such patients should be treated the same as patients with AF of longer duration: 3 to 4 weeks of oral anticoagulation or shorter term anticoagulation with screening TEE prior to elective electrical or pharmacological cardioversion, followed by prolonged anticoagulation therapy after cardioversion.

Rate Control

Pharmacologic Therapy

Ventricular rate control during AF is important to prevent hemodynamic instability, improve symptoms and functional capacity, improve quality of life, and, over the long-term, prevent tachycardia-mediated cardiomyopathy. Oral or intravenous (IV) atrioventricular node (AVN) blockers are used for rate control, depending on the severity of symptoms and the degree of hemodynamic compromise caused by the tachycardia. In addition, correction of secondary causes of fast ventricular rates during AF (e.g., infection, hyperthyroidism, anemia, pain, and pulmonary embolism) is essential to achieve adequate rate control.⁵⁵

Beta-blockers or nondihydropyridine calcium channel blockers (verapamil and diltiazem) are the drugs of choice for rate control, and appear to have equivalent efficacy. Care should be used in administering those medications in patients with acutely decompensated heart failure. Beta-blockers are preferred in patients with cardiomyopathy, ischemic heart disease, and following surgical procedures. Verapamil and diltiazem are preferred in patients with reactive airway disease.^{4,55}

Digoxin is less effective and requires a longer time to achieve rate control, but may be considered if beta-blockers and calcium channel blockers have failed or have intolerable side effects. While digoxin reduces the resting heart rate, it is seldom effective in ambulatory patients because its effects are mediated by enhancement of vagal tone, which is offset during exertion. Thus digoxin has traditionally been used as a second-line agent, usually in sedentary patients or those with heart failure or hypotension. Recently, however, several systematic reviews and meta-analyses found that digoxin use was independently associated with a greater risk for mortality in patients with AF, regardless of concomitant heart failure. Some studies have suggested that AF nullifies the effect of digoxin in reducing hospitalizations for heart failure patients. Hence, the long-term use of digoxin is discouraged.^{124–128}

Amiodarone can be considered for rate control when other AVN blockers are unsuccessful or not tolerated. IV amiodarone is useful for acute control of the ventricular rate, and can be of particular value in acutely ill patients or those with acutely decompensated heart failure or severe hemodynamic compromise. Because of the probability of termination of AF by amiodarone, though very small, pericardioversion anticoagulation strategies should be considered, depending on the individual patient's risk/benefit profile. Oral amiodarone can be useful for ventricular rate control when other measures are unsuccessful or contraindicated; however, long-term potential toxicity should be carefully considered.¹²⁹

In patients with AF and ventricular preexcitation causing rapid ventricular response, prompt direct-current cardioversion is recommended, especially when hemodynamic compromise is present. IV procainamide or ibutilide to restore NSR or slow the ventricular rate can be considered in hemodynamically stable patients. Importantly, drugs that preferentially slow AVN conduction without prolonging BT refractoriness (such as verapamil, diltiazem, adenosine, oral or IV digoxin, and IV amiodarone) can accelerate the ventricular rate and potentially precipitate hemodynamic collapse and VF in high-risk patients. Unlike the IV route of administration, chronic oral amiodarone therapy can slow or block BT conduction. Limited data exist regarding the use of beta-blockers; nonetheless, these drugs theoretically pose a similar potential risk and they should be used with caution.¹³⁰

Adequacy of rate control should be assessed at rest and with exertion. However, parameters for optimal rate control in AF remain controversial. It appears reasonable to target a resting heart rate of 60 to 80 beats/min and 90 to 115 beats/min during moderate exercise. Ambulatory monitoring can help assess adequacy of rate control; goals of therapy include a 24-hour average heart rate lower than 100 beats/min and no heart rate higher than 100% of the maximum age-adjusted predicted exercise heart rate. Also, a maximum heart rate of 110 beats/min during a 6-minute walk test is a commonly used target. Nonetheless, one study found that a more lenient rate control (resting heart rate less than 110 beats/min) is not inferior to strict rate control (heart rate less than 80 beats/min at rest and less than 110 beats/min during moderate exercise). Such an approach can be more convenient in clinical practice and can be considered especially in asymptomatic patients with permanent AF and no significant structural heart disease, but periodic monitoring of LV function is necessary to evaluate for the potential risk of tachycardia-mediated cardiomyopathy. Of note, lenient rate control does not seem to increase the risk of adverse atrial or ventricular remodeling.⁴

In some patients with SND or tachycardia-bradycardia syndrome, pacemaker implantation can be required to protect from severe bradycardia while allowing the use of AVN blockers for adequate control of fast ventricular rates during AF or the use of antiarrhythmic drug therapy for maintenance of NSR (see Fig. 8.6). In one report, nearly 20% of patients with AF required pacemaker placement for symptomatic bradycardia, most within 5 years of their AF diagnosis, which was especially common in those with a history of heart failure. In patients with SND, atrial or dual-chamber pacing significantly decreases the incidence of subsequent AF compared with ventricular pacing.¹³⁰

Atrioventricular Junction Ablation

Ablation of the AV junction combined with permanent pacemaker implantation (the “ablate and pace” approach), provides robust control of ventricular rate as well as regularization of the R-R interval. However, because it is permanent and mandates lifelong pacing, AV junction ablation usually is considered as a last resort approach in AF patients when rhythm control strategies fail and pharmacological rate control therapy is poorly tolerated or unsuccessful. AV junction ablation is

especially useful when excessive ventricular rates induce a tachycardia-mediated decline in LV systolic function, despite appropriate medical therapy.

Furthermore, among patients with LV systolic dysfunction and AF, AV junction ablation has emerged as an important adjunctive therapy for cardiac resynchronization recipients. It has been estimated that 20% to 25% of those eligible for cardiac resynchronization have AF, and the cumulative incidence of new-onset AF/ATs ranges between 20% and 40% according to device interrogations. In patients with permanent AF or frequent persistent or paroxysmal arrhythmia episodes despite attempts to maintain NSR, intrinsic ventricular rate during AF (even though within the normal range) can override the biventricular pacing rate and reduce the percentage of effectively biventricular paced QRS complexes, thus precluding optimal ventricular resynchronization. Ablation of the AV junction in this setting has been associated with a reduction in all-cause mortality, a reduction in cardiovascular mortality, and an improvement in LVEF compared with those patients who were managed medically. It is important to note that the percentage of biventricular pacing determined by device counters often is artificially high because of invalid counting of fusion (hybrid between paced and intrinsic QRS morphologies) and pseudo-fusion complexes (pacing artifacts delivered but intrinsic QRS morphology not altered). In these patients, exercise ECG testing can help detect loss of effective ventricular synchronization and determine the percentage of pure biventricular pacing. AV junction ablation can also be required in ICD patients experiencing inappropriate therapies triggered by fast ventricular rates during AF.⁴

Rhythm Control

Restoration and maintenance of NSR in patients with AF can have several potential benefits, including relief of symptoms, improved functional status and quality of life, and prevention of tachycardia-induced cardiomyopathy. Attenuation of electrical and structural atrial remodeling associated with AF (and hence retarding the progression of AF), and improvement in LV function also have been described. The impact of rhythm control on mortality, however, remains to be determined.

Unfortunately, complete maintenance of NSR (i.e., 100% freedom from AF recurrence) often is unachievable with current drug therapies and remains an impractical treatment goal. It has been estimated that the average 1-year recurrence rate associated with amiodarone approximates 35%, and the recurrence rates for other currently available antiarrhythmic drug therapies are even higher (more than 50%). However, it is likely that individuals with AF can derive benefit from even partial restoration of NSR.

Reversion to Normal Sinus Rhythm

When rhythm control strategy is chosen, both electrical and pharmacological cardioversion methods are appropriate options. The timing of attempted cardioversion is influenced by the duration of AF, severity of patient's symptoms, adequacy of rate control, and risk of thromboembolism. Prompt cardioversion is recommended for patients with rapid ventricular rates and hemodynamic compromise attributed to AF (hypotension, acute heart failure, myocardial ischemia) or ventricular preexcitation, when rate-control drug therapy is unsuccessful or not tolerated. Cardioversion is also considered to restore NSR in stable but symptomatic patients with persistent AF, especially when ventricular rate control remains suboptimal.

Timing of cardioversion. In stable patients with AF of a duration longer than 48 hours or of unknown duration, any mode of cardioversion (electrical, pharmacological, or ablation) should be delayed until the patient has been anticoagulated at appropriate levels for 3 to 4 weeks or TEE has excluded atrial thrombi, regardless of the CHA₂DS₂-

VASc score. TEE can also be considered in patients with high thrombotic risk (e.g., severe valvular or congenital heart disease, prior thromboembolic events, severe cardiomyopathy), even when the duration of AF is less than 48 hours.¹²⁹

If urgency of cardioversion (because of severe symptoms or hemodynamic instability) precludes TEE, therapeutic doses of low-molecular-weight heparin, unfractionated heparin, or a non-vitamin K oral anticoagulant should be administered as soon as possible concurrent with or, preferably prior to, cardioversion, followed by long-term anticoagulation therapy.⁴

Electrical cardioversion. The overall success rate of electrical cardioversion for AF is about 90% and is inversely related to the duration of AF and LA size. The initial use of maximum-energy shocks, biphasic waveform, and anterior-posterior (as opposed to anterior-left lateral) electrode placement can help improve the efficacy of cardioversion and minimize the number of shocks required and, hence, the duration of sedation. In AF patients with ICDs, the electrodes should ideally be placed at least 8 cm away from the device in an anterior-posterior arrangement. The ICD can be used for internal cardioversion; however, the success rate is far lower than with external cardioversion, and each shock uses about 2 weeks of battery capacity.

Occasionally, electrical cardioversion fails to terminate AF, or AF recurs shortly after transient restoration of NSR. It is important to distinguish failure to terminate AF with a certain shock energy from successful termination of AF with nearly immediate recurrence. When AF fails to terminate, using higher energy levels, delivering a biphasic rather than monophasic waveform, applying external pressure on the cardioversion patches, changing the shock vector by altering the electrode pad position, and performing cardioversion during exhalation can improve effectiveness in some patients.

When AF recurs early after a successful cardioversion, repeated shocks at any energy are unlikely to have greater benefit. On the other hand, pretreatment with amiodarone, dofetilide, flecainide, ibutilide, propafenone, or sotalol can enhance success of electrical cardioversion and prevent early AF recurrence. In addition, pretreatment with a drug such as ibutilide can help lower the defibrillation threshold. The administration of IV magnesium sulfate alone before electric cardioversion does not appear to increase the rate of successful cardioversion of AF.^{4,131}

When the long-term use of antiarrhythmic drug therapy is planned for maintenance of NSR, initiation of drug therapy 1 to 3 days before electrical cardioversion (or a few weeks in the setting of amiodarone) to achieve effective drug levels at the time of cardioversion can help maintain NSR and prevent immediate recurrences of AF following cardioversion. This also confirms that the patient can tolerate the medication from a side effect perspective prior to cardioversion.⁵⁵

Of note, for AF of recent onset (less than 48 hours), newly started (less than 12 hours) AF episodes can be more difficult to terminate with electrical cardioversion than AF episodes lasting 12 to 48 hours, and failure of electrical cardioversion in the acute phase does not predict later successful cardioversion or spontaneous conversion to NSR in these patients.¹³²

Electrical cardioversion is usually preferred to pharmacological cardioversion because of greater efficacy and a low risk of proarrhythmia; however, it requires conscious sedation or anesthesia. Importantly, electrical cardioversion is contraindicated in patients with ongoing toxic reactions from digitalis or patients with hypokalemia.

The incidence of acute arrhythmic complications related to electrical cardioversion is very low. Ventricular arrhythmias needing intervention are extremely rare, irrespective of shock energy output or the concurrent use of antiarrhythmic drugs, although may be more common in patients receiving digitalis. Significant bradyarrhythmias (asystole greater than 5 seconds or heart rate less than 40 beats/min) resulting from

SND and the effect of sedation are observed in about 1% of patients. Almost all external defibrillators have the capability of back-up bradycardia pacing through the defibrillation patches, which can be used transiently if needed. In addition, IV atropine or isoproterenol should be available. Of note, a large proportion (more than 40% in one report) of patients exhibiting severe bradyarrhythmias following successful cardioversion require pacemaker implantation during short-term follow-up.

Pharmacological cardioversion. The efficacy of pharmacological cardioversion of AF is modest (30% to 70%), and is highest when initiated within 7 days of the onset of an episode of AF. While several antiarrhythmic drugs can be used for chemical cardioversion of AF, ibutilide and dofetilide are the most effective agents. Other antiarrhythmic drugs, including sotalol, amiodarone, and class IC agents (e.g., flecainide, propafenone) have limited efficacy. AVN blockers (beta-blockers, digoxin, and calcium-channel blockers) are generally not effective for restoration of NSR.¹²⁹

The risk of proarrhythmia is higher for chemical than electrical cardioversion. Therefore pharmacological cardioversion necessitates continuous cardiac monitoring (to detect SND, AV block, ventricular arrhythmias, and conversion into AF) for an interval that is dependent on the agent used (usually approximately half the drug elimination half-life).

Despite its limited efficacy, pharmacological cardioversion remains an option when sedation (which is required for electrical cardioversion) is not available or not well tolerated or when indicated by patient preference. In addition, as noted previously, when the use of long-term antiarrhythmic medications is planned for maintenance of NSR, starting drug therapy before electrical cardioversion can be beneficial, as it can help restore NSR in some patients and obviate the need for electrical cardioversion and, in other cases, can potentially enhance the efficacy of electrical cardioversion and prevent early recurrence of AF. Importantly, termination of AF may result in unanticipated sinus pauses/asystole with resultant presyncope or syncope, especially when using agents that can suppress sinus node function.

Ibutilide. IV ibutilide can restore NSR in 28% to 51% of AF patients, with an average conversion time of less than 33 minutes. Pretreatment with ibutilide also improves the efficacy of electrical cardioversion. Importantly, ibutilide is associated with sustained polymorphic VT (torsades de pointes) in 1.2% to 2.4% of cases, and nonsustained VT in 1.8% to 6.7%, which is more likely to occur in patients with QT prolongation, marked hypokalemia, or a very low LVEF. Pretreatment with IV magnesium can increase the efficacy and reduce the risk of torsades de pointes.

Dofetilide. Dofetilide can convert persistent AF to NSR in up to 60% of patients, typically within 36 hours of drug initiation. Dofetilide is rarely used solely for the purpose of cardioversion; rather, it is typically initiated for long-term rhythm control. When initiated in patients with persistent AF, electrical cardioversion is usually delayed for 24 to 48 hours to allow for potential pharmacological cardioversion. Of note, AF termination during dofetilide loading appears to be a predictor of durable response, even in longstanding persistent patients. Dofetilide is not available in Europe.

Amiodarone. Amiodarone has very limited efficacy (approximately 25%) in terminating persistent AF, and is not a preferred agent solely for the purpose of cardioversion. When successful, conversion to NSR occurs several hours or days after initiation of IV amiodarone, and after days to weeks of long-term loading of oral amiodarone.

Flecainide and propafenone. The class IC agents flecainide and propafenone can be used for pharmacologic cardioversion of AF; successful conversion to NSR typically occurs within 8 hours. The efficacy of flecainide for pharmacological cardioversion of recent-onset (less

than 24 hours) AF is significantly higher than that of amiodarone, sotalol, procainamide, and propafenone, with conversion rates ranging between 52% and 92% in different reports. In comparison with oral flecainide, IV flecainide is no more effective for pharmacological cardioversion of recent-onset AF, although IV flecainide has a more rapid onset of action (mean time to cardioversion 55 vs. 110 minutes). Propafenone (IV or oral) can be used for the acute termination of AF (rate of conversion to NSR ranges from 56% to 83%). IV preparations of flecainide and propafenone are not available in the United States. Importantly, the use of class IC agents is contraindicated in patients with significant structural heart disease, particularly those with LV systolic dysfunction or coronary artery disease. In addition, class IC drugs can potentially convert AF into AFL with relatively slow atrial rate and, hence, facilitate 1:1 AV conduction and paradoxically faster ventricular rates. Therefore adequate rate control with AVN blockers (beta-blockers, diltiazem, verapamil) should be achieved before instituting antiarrhythmic therapy. Once the safety of pharmacological conversion with propafenone or flecainide has been established in the hospital setting, repeat patient-administered cardioversion using oral propafenone (450 to 600 mg) or flecainide (200 to 300 mg), in addition to a beta-blocker or nondihydropyridine calcium channel blocker, can be appropriate on an outpatient basis (the “pill-in-the-pocket” approach). This approach is usually employed in selected patients with infrequent symptomatic episodes of AF lasting at least several hours at a time and recurring less than once a month.

Vernakalant. Vernakalant has been approved in Europe for the cardioversion of recent-onset AF (duration less than or equal to 7 days for patients not undergoing surgery, and less than or equal to 3 days for postcardiac surgery patients). IV vernakalant offers an AF conversion rate of about 62% within 90 minutes and appears to be much more effective than IV amiodarone. Some studies have also suggested its superiority to flecainide and propafenone. Vernakalant is not available in the United States.¹³³

Other antiarrhythmic agents. Sotalol, dronedarone, quinidine, and procainamide offer very low efficacy for acute termination of AF, and are not recommended for pharmacological cardioversion.

Maintenance of Normal Sinus Rhythm

Only 20% to 30% of patients who are successfully cardioverted maintain NSR for more than 1 year without chronic antiarrhythmic therapy. This is more likely to occur in patients with AF for less than 1 year, no enlargement of the LA (less than 4.0 cm), and a reversible cause of AF (such as hyperthyroidism, pericarditis, pulmonary embolism, or cardiac surgery). It has been thought that the drugs most likely to maintain NSR suppress triggering ectopic beats and arrhythmias and affect atrial EP properties to diminish the likelihood of AF. There is therefore a strong rationale for antiarrhythmic drug therapy in patients who have a moderate to high risk of recurrence, provided that the therapy is effective and that toxic and proarrhythmic effects are low. Prophylactic drug treatment is seldom indicated in patients with a first-detected episode of AF and can also be avoided in patients with infrequent and well-tolerated paroxysmal AF.

Amiodarone has been directly compared to dronedarone, sotalol, and propafenone and found to be substantially more effective, with a 1-year rate of maintaining NSR of 65%. Dofetilide offers 50% to 65% efficacy in maintaining NSR at 1 year. Other antiarrhythmic agents have only modest efficacy (30% to 50% at 1 year). Drug selection is largely driven by the safety profile, the presence and extent of concomitant cardiovascular disease, hepatic and renal dysfunction, and drug-drug interactions. A safer, although possibly less efficacious, drug is usually recommended before resorting to more effective but less safe therapies (Fig. 15.8; Table 15.14).¹³⁴

Fig. 15.8 Strategies for Rhythm Control in Patients With Paroxysmal and Persistent Atrial Fibrillation. Drugs are listed alphabetically. ^aCatheter ablation is only recommended as first-line therapy for patients with paroxysmal AF (class IIa recommendation), depending on patient preference when performed in experienced centers. ^bNot recommended with severe LVH (wall thickness greater than 1.5 cm). ^cShould be used with caution in patients at risk for torsades de pointes ventricular tachycardia. ^dShould be combined with AV nodal blocking agents. AF, Atrial fibrillation; AV, atrioventricular; CAD, coronary artery disease; HF, heart failure; LVH, left ventricular hypertrophy. (From January CT, Wann LS, Alpert JS, et al. 2014 AHA/ACC/HRS guideline for the management of patients with atrial fibrillation: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines and the Heart Rhythm Society. *J Am Coll Cardiol.* 2014; 64:e1–e76.)

TABLE 15.14 Most Commonly Used Antiarrhythmic Drugs for the Treatment of Atrial Fibrillation

Antiarrhythmic Drug	Year of Approval	Channels Blocked	Noncardiovascular Toxicity	Cardiovascular Toxicity
Flecainide	1975	INa	Dizziness, headache, visual blurring	AFL with 1:1 conduction; VT; may unmask Brugada-type ST elevation
Propafenone	1976	INa, β -AR	Metallic taste, dizziness, visual blurring	AFL with 1:1 conduction; VT; may unmask Brugada-type ST elevation
Sotalol	1992	IKr, β -AR	Bronchospasm	Bradycardia, torsades de pointes
Amiodarone	1967	IKr, INa, ICaL, IKur, Ito, IKACH If, β -AR, α -AR	Pulmonary (acute hypersensitivity pneumonitis, chronic interstitial infiltrates); hepatitis; thyroid (hypothyroidism or hyperthyroidism); photosensitivity; blue-gray skin discoloration; nausea; ataxia; tremor; alopecia	Sinus bradycardia
Dronedaron	2009	IKr, INa, ICa, IKur, Ito, IKACH If, β -AR, α -AR	Anorexia; nausea; hepatotoxicity	Bradycardia
Dofetilide	2000 (US only)	IKr	None	Torsades de pointes
Disopyramide	1962	INa, IKr, Acetylcholine	Anticholinergic: dry mouth, urinary retention, constipation, blurry vision	CHF exacerbation, torsades de pointes

AFL, Atrial flutter; AR, adrenoceptor; CHF, congestive heart failure; ICaL, L-type Ca^{2+} current; If, funny current; IKACH, acetylcholine-activated inward rectifier K^{+} current; IKr, rapidly activating delayed rectifier K^{+} current; IKur, ultra-rapidly activating delayed rectifier K^{+} current; Ito, transient outward K^{+} current; INa, Na^{+} current; VT, ventricular tachycardia.

In patients with AF and minimal or no heart disease, flecainide, propafenone, sotalol, and dronedaron are preferred; amiodarone should be chosen later in the sequence of drug therapy because of its potential toxicity. In patients with adrenergically mediated AF, beta-blockers represent first-line treatment, followed by sotalol. The anticholinergic activity of long-acting disopyramide makes it a relatively attractive

choice for patients with vagally mediated AF. In contrast, propafenone is not recommended in vagally mediated AF because its (weak) intrinsic beta-blocking activity may aggravate this type of paroxysmal AF.

In patients with substantial LV hypertrophy (LV wall thickness greater than 1.4 cm), it is recommended to avoid sotalol, flecainide, and propafenone because of concern of increased proarrhythmic risk. Dronedaron,

although not specifically tested in this population, is likely to be safe. Amiodarone is usually considered when symptomatic AF recurrences continue to affect the quality of life in these patients.

In patients with coronary artery disease, sotalol, dofetilide, or dronedarone are recommended as first-line therapy, while flecainide and propafenone are contraindicated. Amiodarone is considered the drug of last resort in this population because of its potential toxicity.

Dofetilide and amiodarone are the only agents available for patients with AF with concomitant heart failure; other antiarrhythmic agents can be associated with substantial toxicity and proarrhythmia.

Quinidine is associated with increased mortality, likely the result of ventricular proarrhythmia secondary to QT interval prolongation. Hence, this drug has largely been abandoned for AF therapy.

Given the suboptimal efficacy of antiarrhythmic drug therapy, expectations and treatment goals have to be pragmatic. Reduction of the burden of AF and its impact on quality of life can be a reasonable outcome. Occasional AF recurrences may not require a change in antiarrhythmic drug therapy. When treatment with a single drug fails, combinations of antiarrhythmic drugs can be tried. Useful combinations include sotalol or amiodarone in addition to a class IC agent. However, when drug therapy is deemed unsuccessful and a rhythm control strategy is abandoned, antiarrhythmic drug should not be continued.

Amiodarone. Amiodarone, although not approved by the US Food and Drug Administration for AF, is the most commonly prescribed and the most effective antiarrhythmic agent for the treatment of AF. However, the use of amiodarone is associated with significant adverse effects (including pulmonary, hepatic, thyroid, neurologic, and ophthalmic toxicity). QT prolongation is common but very rarely associated with torsades de pointes (0.5%). Although suppression of sinus and AV nodal function can occur early within the first few days of oral amiodarone therapy, the antiarrhythmic effect and QT prolongation can be delayed for days or weeks. A loading phase accelerates the onset of its antiarrhythmic activity. Amiodarone increases concentrations of warfarin, statins, and digoxin, and warfarin dose adjustment is often necessary. Appropriate periodic surveillance for lung, liver, and thyroid toxicity is required. Because of its potential toxicities, amiodarone should only be used after consideration of risks and when other agents have failed or are contraindicated.

Dofetilide. Dofetilide offers up to 65% efficacy in maintaining NSR at 1 year. Dofetilide has been demonstrated to be reasonably safe in heart failure and post-MI populations. However, because of the risk of QT prolongation and VT, initiation of dofetilide requires a 3-day mandatory in-hospital loading period under continuous telemetry and ECG monitoring. Excessive QT prolongation or VT prompting drug discontinuation during the loading period has been reported in almost 20% of the patients. Concomitant usage of other QT-prolonging drugs increases the risk of these adverse events by almost twofold. Overall, the risk of torsades de pointes in patients receiving dofetilide ranges from 0.7% to 3.3%. In a retrospective cohort study of 1404 AF patients treated with dofetilide for a 5-year period, the incidence of torsades de pointes was 1.2%. Risk predictors included female gender, low LVEF, and greater QTc prolongation. Dofetilide is not approved in Europe.

Flecainide and propafenone. Class IC agents are preferred first-line agents for rhythm control in patients with AF without structural heart disease, in whom both drugs are well tolerated and have a low risk of toxicity. On the other hand, these agents are contraindicated in patients with marked LV hypertrophy, coronary artery disease, or heart failure because of the risk of ventricular arrhythmias. Further, both flecainide and propafenone exhibit negative inotropic effects and should be avoided in patients with LV dysfunction. As noted previously, propafenone and flecainide are associated with a significant incidence of AFL

with relatively slow atrial rate, which can be associated with 1:1 AV conduction and very fast ventricular rates; therefore adequate rate control with AVN blockers is recommended before instituting class IC drug therapy. In addition, class IC agents can delay His-Purkinje system (HPS) conduction and prolongation of the QRS duration, which when excessive (more than 25% compared with baseline) can be a marker for proarrhythmia risk.

Sotalol. Sotalol has only modest efficacy in maintaining NSR (30% to 50% at 1 year). Sotalol causes drug-induced QT prolongation and torsades de pointes, especially in the setting of renal failure, hypokalemia, or the concomitant use of other QT-prolonging drugs. Therefore sotalol is often initiated in an inpatient setting with ECG monitoring to observe for excessive QT prolongation and proarrhythmia, especially when the drug is initiated during AF. However, drug initiation in an outpatient setting is also common, especially in low-risk patients with no underlying structural heart disease, QTc less than 450 milliseconds, normal electrolytes and renal function, and are in NSR at the time of drug initiation. Sotalol can be used in patients with ischemic heart disease, but should be avoided in patients with marked LV hypertrophy and those with renal insufficiency.

Dronedarone. Dronedarone is a structural analogue of amiodarone that lacks the iodine moieties. Although dronedarone is associated with a lower incidence of noncardiovascular side effects than amiodarone, it is significantly less efficacious. The major cardiac adverse effects of dronedarone are bradycardia and QT prolongation. Torsades de pointes is rare but has been reported. Dronedarone can be used for AF in patients without structural heart disease, but is contraindicated (because of increased mortality) in patients with NYHA class III or IV heart failure and in patients who have had a recent (in the past 4 weeks) episode of decompensated heart failure, especially in the presence of LV systolic dysfunction. In patients with permanent AF, dronedarone increases the combined endpoint of stroke, cardiovascular death, and hospitalization. Therefore dronedarone is contraindicated in patients whose sinus rhythm is not restored.

Disopyramide. Disopyramide is a sodium channel-blocking drug with potent anticholinergic and negative inotropic effects that can be considered for rhythm control in patients with AF. Because of its prominent vagolytic effects, disopyramide can be useful in “vagally mediated” AF (e.g., AF occurring in athletes or during sleep). Also, its negative inotropic effects make disopyramide beneficial in treating AF in patients with hypertrophic cardiomyopathy (HCM) associated with dynamic left ventricular outflow tract (LVOT) obstruction; however, these effects preclude its use in patients with underlying LV systolic dysfunction.

Rhythm Control Versus Rate Control

In the past, many physicians preferred rhythm control to rate control. Reversion of AF and maintenance of NSR restores normal hemodynamics and had been thought to reduce the frequency of embolism. However, two major randomized clinical trials—AFFIRM (Atrial Fibrillation Follow-Up Investigation of Rhythm Management) and RACE (Rate Control versus Electrical Cardioversion for Persistent Atrial Fibrillation)—compared rhythm and rate control in a select population at moderate stroke risk and found that embolic events occurred with equal frequency, regardless of whether a rate control or rhythm control strategy was pursued, and this occurred most often after warfarin had been stopped or when the INR was subtherapeutic. Both studies also showed an almost significant trend toward a lower incidence of the primary endpoint with rate control strategy. There was no difference in the functional status or quality of life. Hence, those trials provided evidence that both rhythm control and rate control are reasonable approaches (both strategies requiring long-term anticoagulation for stroke prevention), and suggested that rate control is an acceptable

approach in most patients. The AF-Congestive Heart Failure (AF-CHF) study demonstrated similar results among patients with AF with concomitant heart failure. The results of those randomized controlled comparisons of rhythm and rate control therapies were confirmed by more recent observation studies, registries, and meta-analyses.^{135,136}

However, it would be incorrect to extrapolate that NSR offers no benefit over AF and that effective treatments to maintain NSR need not be pursued. First, these trials were not comparisons of NSR and AF; they compared a rate control strategy to a rhythm control strategy that attempted to maintain NSR but fell short, and crossover between treatment arms occurred at a high rate. The failure of AFFIRM and RACE trials in showing any difference between rate and rhythm control is not so much a positive statement for rate control but rather a testimony to the ineffectiveness of antiarrhythmic drug therapy in maintaining NSR over the long term. When the data from these trials were analyzed according to the patient's actual rhythm (as opposed to his or her treatment strategy), the benefit of NSR over AF became apparent: the presence of NSR was found to be one of the most powerful independent predictors of survival, along with the use of warfarin, even after adjustment for all other relevant clinical variables. Patients in NSR are almost half as likely to die compared with those with AF. This benefit, however, is offset by the use of antiarrhythmic drug therapy, which increases the risk of death.¹³⁶

Therefore achieving and maintaining NSR remain viable and important treatment goals. However, because currently available antiarrhythmic agents commonly fail to suppress AF completely and have safety profiles that are less than ideal, it is reasonable to reserve it to the populations of patients likely to derive the greatest benefit from rhythm control. The selection of rhythm control or rate control strategies should be individualized and take into consideration the nature, intensity, and frequency of symptoms, patient preferences, comorbid conditions, and the risk of recurrent AF. According to analyses of available data, rhythm control can be an appropriate approach in young AF patients and those with newly diagnosed AF, significant symptoms, poorly controlled ventricular response, or tachycardia-mediated cardiomyopathy. On the other hand, asymptomatic or mildly symptomatic patients, especially those older than 65 years, and women with persistent AF who have hypertension or other underlying heart diseases can be better suited for rate control therapy.¹³⁷

It is important to note that current guidelines do not routinely recommend a rhythm control strategy for reducing the risk of mortality, stroke, or heart failure; rather, the primary indication for rhythm control therapy is for the reduction of symptoms and improvement in quality of life.¹³⁵

Catheter Ablation of Atrial Fibrillation

Catheter ablation of AF provides higher efficacy with comparable safety as antiarrhythmic drug therapy. AF ablation has been shown to significantly improve symptoms, exercise capacity, quality of life, and LV function, even in the presence of concurrent heart disease and when ventricular rate control has been adequate before ablation. Catheter ablation was also found to be associated with better quality of life, higher rates of freedom from both AF and antiarrhythmic medications, and lower rates of AF progression when compared with AVN ablation and biventricular pacing in symptomatic patients with AF and cardiomyopathy (LVEF less than or equal to 40%). Further, a recent study found that catheter ablation of AF superior to medical rate control strategy in patients with idiopathic cardiomyopathy, with significant improvement in the LVEF; restoration of NSR with catheter ablation resulted in significant improvements in LV systolic function, particularly in the absence of ventricular fibrosis on CMR. However, evidence is insufficient to determine whether AF ablation reduces all-cause mortality or stroke. Therefore the primary

justification for an AF ablation procedure at this time is the presence of symptomatic AF.^{1,55,130,138,139}

At the current time, patient selection criteria for AF ablation should include weighing risks and potential benefits associated with the procedure, as well as consideration of other factors such as severity of symptoms, quality of life, presence and severity of structural heart disease and other comorbidities, and availability of other reasonable treatment options. In addition, the projected ablation success rate with the operator's own experience and the tools available to him or her should be taken into consideration.

The ideal candidate for catheter ablation of AF has symptomatic episodes of paroxysmal or persistent AF, has not responded to one or more class I or III antiarrhythmic drugs, does not have severe comorbid conditions or severe structural heart disease, has an LA diameter smaller than 50 to 55 mm and, for those with longstanding AF, has had AF for less than 5 years. Catheter ablation of AF is likely to be of little or no benefit in patients with end-stage cardiomyopathy or massive enlargement of the LA (more than 60 mm), or in patients who have severe mitral regurgitation or stenosis and are deemed inappropriate candidates for valvular intervention. With improvements in the efficacy and safety of the procedure, the inclusion criteria for catheter ablation of AF continue to evolve; expanded indications at many centers now include patients with longstanding persistent AF and those with cardiomyopathy.^{130,138}

Current guidelines recommend catheter ablation in patients with symptomatic paroxysmal or nonparoxysmal AF as a second-line treatment after failure of or intolerance to class I or III antiarrhythmic drug therapy (Fig. 15.9). It is reasonable to use similar indications for AF ablation in selected patients not well represented in clinical trials, including those with heart failure, cardiomyopathy, younger patients (less than 45 years) and older patients (greater than 75 years). However, the risks and benefits of catheter ablation must be carefully assessed in these patients. A lower success rate or a higher complication rate can be expected in AF patients with concomitant heart disease, obesity, sleep apnea, severe LA dilation, longstanding persistent AF, as well as frail, elderly patients.^{1,55,130,140}

Indication for catheter ablation of symptomatic atrial fibrillation

Fig. 15.9 The 2017 HRS/EHRA/ECAS/APHS/SOLAECE Indications for Catheter Ablation of Symptomatic Atrial Fibrillation (AF). Shown in this figure are the indications for catheter ablation of symptomatic paroxysmal, persistent, and longstanding persistent AF. The class for each indication based on whether ablation is performed after failure of antiarrhythmic drug therapy or as first-line therapy is shown. (From Calkins H, Hindricks G, Cappato R, et al. 2017 HRS/EHRA/ECAS/APHS/SOLAECE expert consensus statement on catheter and surgical ablation of atrial fibrillation. *Heart Rhythm*. 2017;14:e275–e444.)

It is important to recognize that there are still no randomized controlled data demonstrating that a patient's stroke risk is reduced by ablation. Therefore AF catheter ablation should not be performed with the sole intent of obviating the need for anticoagulation.^{1,130}

Complications of catheter ablation can have catastrophic outcomes in certain patients, including those with severe obstructive carotid artery disease, cardiomyopathy, aortic stenosis, nonrevascularized left main or three-vessel coronary artery disease, severe pulmonary arterial hypertension, or hypertrophic cardiomyopathy with severe LV outflow obstruction. Another relative contraindication is a history of major lung resection because of the severe impact of potential PV stenosis. Furthermore, because of the risk of thromboembolic events during the procedure and in the early postoperative period, patients who cannot be anticoagulated during and for at least 2 months after the ablation procedure should not be considered for catheter ablation of AF. Also, catheter ablation should not be performed in patients with an LAA thrombus or a recently implanted LAA closure device.

Catheter ablation as first-line therapy. Recent studies have demonstrated superior efficacy of catheter ablation as a first-line therapy as compared to pharmacological therapy, though most patients enrolled in those studies were generally healthy with predominantly paroxysmal AF. According to the 2017 HRS/EHRA/ECAS/APHRS/SOLAECE expert consensus statement, it is reasonable to consider catheter ablation as a first-line rhythm-control treatment (before therapeutic trials of class I or III antiarrhythmic drug therapy) for AF in select patients with symptomatic paroxysmal or persistent AF who prefer interventional therapy (see Fig. 15.9). This approach can be of particular value when poor tolerance to antiarrhythmic drugs is anticipated, such as in patients with tachycardia-bradycardia syndrome in whom pharmacological rhythm control strategies would necessitate pacemaker implantation. Similarly, catheter ablation is often recommended as an initial approach in high-level competitive athletes with paroxysmal or persistent AF in whom pharmacologic therapy can negatively affect athletic performance. The efficacy of this approach in unselected patient populations, however, still awaits confirmation by randomized studies, and the risk-benefit ratio of this approach in the individual patient should be carefully considered.^{1,140}

Catheter ablation for asymptomatic AF. Symptoms of persistent AF can be quite subtle and nonspecific (e.g., lack of energy, effort intolerance) and may not be recognized by the patients or can be attributed to other comorbidities (such as sleep apnea or heart failure). Before labeling AF patients as “asymptomatic,” it is important to obtain a careful history to elicit symptoms. Also it is appropriate to attempt restoration of NSR (with electrical or pharmacological cardioversion, with or without long-term antiarrhythmic drug therapy) and then assess the patient's symptom status while in NSR as compared to AF. Despite the lack of overt symptoms, AF ablation can still be a feasible way to improve well-being in these patients.¹

In addition, catheter ablation of AF may still be considered (class IIB) in select patients with truly asymptomatic paroxysmal or persistent AF (those who did not experience any improvement during a “trial of NSR”) when performed by an experienced operator and following a detailed discussion of the risks and benefits. The patient should be informed that AF, whether symptomatic or asymptomatic, is associated with an increased risk of stroke, heart failure, dementia, and mortality, and while it is possible that maintenance of NSR with AF ablation can potentially reduce these risks, these potential benefits remain unproven. Deferring ablation while awaiting the results of clinical trials can potentially allow progression of AF to a stage when the efficacy of AF ablation is significantly reduced. Importantly, while this approach can be acceptable in select asymptomatic patients, it is not recommended for patients with longstanding persistent AF and those with clinical whose clinical profile would be associated with a low procedural efficacy and safety.¹

Surgical Ablation of Atrial Fibrillation

The classic Cox-maze procedure involves creating a series of incisions in the left and right atria designed to direct the propagation of the sinus impulse through both atria while interrupting the multiple macroreentrant circuits thought to be responsible for AF. This procedure is the most effective means of curing AF, eliminating the arrhythmia in 75% to 95% up to 15 years after surgery. Improvements and simplifications of the surgical technique culminated in the Cox-maze III procedure, which became the gold standard for the surgical treatment of AF. Nonetheless, because of its complexity, technical difficulty, and risk of mortality and other complications, the maze procedure did not gain widespread acceptance.¹

To simplify the procedure, the standard cut-and-sew surgical technique has been replaced with linear epicardial ablation using unipolar or bipolar RF ablation, cryoablation, laser, high-frequency ultrasound, or microwave energy. Most surgical epicardial ablation procedures have been performed in conjunction with mitral valve surgery; the combination of mitral valve repair and cure of AF can enable selected patients to avoid life-long anticoagulation.

Current surgical instrumentation now enables minimally invasive approaches to be performed epicardially on the beating heart through mini-thoracotomies with video assistance. Bipolar RF is the predominant energy source used, and bilateral PV isolation is the most common lesion set, with some approaches adding ganglionic plexus ablation, as well as exclusion of the LAA. However, despite elimination of the need for median sternotomy and cardiopulmonary bypass, these procedures are still relatively invasive. To minimize the invasiveness of the procedure further, a totally thoracoscopic approach has been developed. Although multiple series described high success rates for paroxysmal AF (89% at 12 months of follow-up), success has been limited in patients with persistent and longstanding persistent AF (25% to 87%). In one report, the overall complication rate was 10%, with a perioperative mortality rate of 1.8%.¹

More extensive ablation lines, in addition to PV antral isolation and ganglionic plexus ablation, as well as documentation of complete PV isolation by demonstration of EP entrance or exit block, conduction block across ablation lines, and the detection and confirmation of ablation of the parasympathetic component of the ganglionic plexuses, are being evaluated to improve outcome. Some series reported a single procedure success rate of 86% at 1 year without the use of antiarrhythmic drugs.

Surgical ablation of AF is recommended in patients undergoing concomitant open heart surgery (whether ablation is performed after failure of antiarrhythmic drug therapy or as first-line therapy and regardless of the duration of the arrhythmia). Such an approach is also reasonable in patients undergoing closed cardiac surgery (e.g., coronary bypass or surgery) (Fig. 15.10).

Currently, stand-alone and hybrid surgical AF ablation can be considered for symptomatic patients with AF who were refractory to one or more attempts at catheter ablation or who are not candidates for catheter ablation (e.g., patients not candidates for long-term anticoagulation and those with an LA thrombus). Although surgical ablation was found in one report to have superior efficacy to catheter ablation, the complication rate after surgical ablation was higher. Hence, the decision to recommend surgical AF ablation before considering catheter ablation for patients with symptomatic AF refractory to drug therapy and no other indication for cardiac surgery remains controversial, and it should be based on institutional experience with both techniques, the relative outcomes and risks of each in the individual patient, as well as patient preference (see Fig. 15.10). Given the degree of patient discomfort, longer hospitalizations and recovery times, and the risk of bleeding following surgery, most patients prefer catheter to surgical ablation.^{1,130}

Fig. 15.10 The 2017 HRS/EHRA/ECAS/APHS/SOLAECE Indications for Surgical Ablation of Atrial Fibrillation (AF). Shown in this figure are the indications for surgical ablation of paroxysmal, persistent, and longstanding persistent AF. The class for each indication based on whether ablation is performed after failure of antiarrhythmic drug therapy or as first-line therapy is shown. The indications for surgical AF ablation are divided into whether the AF ablation procedure is performed concomitantly with an open surgical procedure (such as mitral valve replacement), a closed surgical procedure (such as coronary artery bypass graft [CABG] surgery), or as a stand-alone surgical AF ablation procedure performed solely for treatment of AF. AVR, Aortic valve replacement. (From Calkins H, Hindricks G, Cappato R, et al. 2017 HRS/EHRA/ECAS/APHS/SOLAECE expert consensus statement on catheter and surgical ablation of atrial fibrillation. *Heart Rhythm*. 2017;14:e275–e444.)

Other Nonpharmacological Approaches for Rhythm Control

Atrial antitachycardia pacing. Several pacing algorithms have been developed to inhibit the initiation of AF episodes. These include continuous atrial pacing just faster than the intrinsic sinus rate, overdrive atrial pacing after a PAC, algorithms for preventing pauses after PACs, and overdrive atrial pacing after the termination of an episode of AF to suppress an early arrhythmia recurrence. A multitude of studies tested the efficacy of those algorithms and showed no consistent reduction in AF burden or improvement in AF symptoms. Similarly, dual-site atrial pacing and atrial septal pacing site did not show benefits.

Modern pacemakers are equipped with a variety of atrial antitachycardia pacing (ATP) algorithms designed to terminate atrial tachyarrhythmias. ATP is delivered at an atrial CL shorter than the detected arrhythmia with the administration of a number of pulses of fixed duration (burst pacing), or sequences at progressively shorter intervals (ramp pacing) to abort episodes of AFL or AT. Prior generations of ATP algorithms demonstrated a modest efficacy (30% to 60%) in terminating slow regular ATs, less effective with rapid ATs, and ineffective at treating established AF. Further, the clinical impact of these algorithms on the burden of the arrhythmia is small. It is important to note that, besides the need for organized atrial tachyarrhythmias, the efficacy of ATP is crucially reliant on early detection of AT and correct rhythm classification by the device.¹³⁰

More recently, a new-generation atrial ATP (“reactive ATP”) was developed to target atrial tachyarrhythmias at onset (when the atrial CL is relatively long) and after any change in rate or regularity when the episode may be most amenable to termination by pacing. Transitions toward more regular or slower rhythms are not infrequent (reportedly occurring in 64% of atrial tachyarrhythmia episodes), even after hours following the onset of the arrhythmia. Unlike standard ATP algorithms, reactive ATP continues to monitor atrial rhythm and watches for any change in rate or regularity, and then opportunistically applies ATP when the episode is most amenable to termination by pacing (eFig. 15.5). In a recent study, reactive ATP reduced the risk of progression of AF to permanent or persistent AF.¹⁴¹

Currently, pacemaker implantation is not indicated for the sole purpose of prevention or treatment of AF in patients without other indications for pacemaker implantation. Nonetheless, ATP offers a therapeutic option for rhythm control in patients with permanent dual-chamber pacemakers or defibrillators that have this feature.

Atrial defibrillators. Atrial defibrillators can terminate AF with high acute success rates, but the need for repeated shocks and the resulting patient discomfort often render this option intolerable. Therefore implanted defibrillators are no longer recommended for rhythm control in AF patients.¹³⁰

Upstream Therapy

Upstream therapy refers to the use of non-ion-channel drug therapy that modifies the atrial substrate upstream of AF to reduce susceptibility to, or progression of, AF. The goal of this approach is attenuation and reversal of atrial structural remodeling to prevent new-onset AF (i.e., primary prevention) or recurrent AF (i.e., secondary prevention). Although some studies demonstrated a potential value of upstream therapy for primary prevention of AF in selected patients, data regarding its value for secondary prevention have been disappointing.⁴⁴

Given the role of fibrosis and inflammation in the pathogenesis of AF, drugs that suppress fibrosis, as well as antiinflammatory and antioxidative drugs, are being investigated both alone and in combination with traditional antiarrhythmic drug therapy. Among these drugs are several angiotensin-converting enzyme inhibitors, angiotensin II type 1 receptor blockers, antialdosterone agents, statins (3-hydroxy-3-methylglutaryl-coenzyme A reductase inhibitors), and omega-3 polyunsaturated fatty acids. These agents seem to reduce atrial fibrosis and

eFig. 15.5 Examples of Atrial Antitachycardia Pacing (ATP). *Upper panel*, Ramp ATP therapy delivered during atrial fibrillation fails at terminating the arrhythmia. *Lower panel*, In the same patient, ramp ATP therapy delivered when the tachycardia transitions into a more organized and slower arrhythmia successfully terminates the tachycardia and restores atrial-paced rhythm within 2 seconds of ATP delivery. AF, Atrial fibrillation; AP, atrial-paced event; AT, atrial tachycardia; TD, tachycardia detection; TP, tachycardia pacing; TS, tachycardia-sensed; VP, ventricular-paced event; VS, ventricular-sensed event.

were found to potentially reduce atrial structural remodeling and AF susceptibility in various AF experimental models. However, clinical trials produced inconclusive results, both for the primary and secondary prevention of AF.⁶¹

Although several studies have suggested a beneficial effect of renin–angiotensin–aldosterone system inhibitors for primary prevention of AF in patients with heart failure and LV systolic dysfunction or hypertrophy, no convincing benefit has been observed in patients without underlying heart disease or for secondary AF prevention. Therefore inhibitors of the angiotensin axis can be considered for AF management when the arrhythmia is associated with other underlying conditions that are themselves associated with myocardial fibrotic remodeling (e.g., LV systolic dysfunction and possibly hypertension with LV hypertrophy), but are not recommended in patients with no apparent cardiovascular disease.^{26,61,137}

No convincing evidence currently exists to support the use of polyunsaturated fatty acids or fish oil for either primary or secondary AF prevention. While some studies demonstrated a protective effect of statins against new-onset AF in patients undergoing coronary artery bypass graft surgery, other studies arrived at conflicting results. On the other hand, short-term colchicine has been associated with lower rates of postoperative AF and reduced early AF recurrence after catheter ablation.^{26,61,137}

Risk Factor Management

There is growing evidence supporting aggressive risk factor modification for primary prevention of AF, management of symptomatic AF, reducing the risk of AF recurrence postablation, and reducing thromboembolic complications of AF (Fig. 15.11). Pursuing and managing hypertension, diabetes, sleep apnea, obesity, and alcohol consumption need to be adopted as a systematic routine in the management of AF patients.^{7,61,44}

Hypertension

Hypertension is an independent risk factor for AF and stroke. Although treatment of hypertension has not been consistently shown to decrease AF risk, it is an important component of reducing cardiovascular complications and thromboembolic risk.⁶¹

Diabetes

Although diabetes is an independent risk factor for the development of AF and thromboembolic complications, there are limited data on diabetes management and AF risk. Intense glycemic control does not appear to directly impact the incidence or course of AF. Nonetheless, optimization of diabetes management and prevention of cardiovascular complications may indirectly reduce risk of AF.^{61,82,83}

Sleep Disordered Breathing

An independent association exists between AF and obstructive sleep apnea. Therefore AF patients should be actively screened for undiagnosed obstructive sleep apnea and evaluated when clinically suspected. Treatment of sleep apnea, when diagnosed, is an important component of AF management. CPAP therapy is associated with more than 40% relative risk reduction in AF recurrence in patients with obstructive sleep apnea, regardless of the AF treatment strategy (pharmacological or invasive).^{61,75}

Lifestyle Modifications

Lifestyle interventions aimed at maintaining a healthy body weight and cardiorespiratory fitness, in the context of a comprehensive risk factor modification, are recommend for both prevention and management of AF. Weight reduction in overweight and obese AF patients, especially those with type II diabetes and hypertension, can improve management of concomitant cardiometabolic risk factors, and was shown to improve symptoms and reduce AF burden.

Fig. 15.11 Risk Factor Management for Prevention of Atrial Fibrillation. ACEI, Angiotensin converting enzyme inhibitor; AHI, apnea–hypopnea index; ARB, angiotensin receptor blocker; BMI, Body mass index; BP, blood pressure; CPAP, continuous positive airway pressure; LDL, low-density lipoprotein; TG, triglyceride. (From Lau DH, Schotten U, Mahajan R, et al. Novel mechanisms in the pathogenesis of atrial fibrillation: practical applications. *Eur Heart J.* 2016;37:1573–1581.)

In addition, regular, moderate exercise appears to benefit overweight and obese patients with symptomatic paroxysmal or persistent AF. One study found a significant dose-response relationship between baseline cardiorespiratory fitness with a 20% reduction in the risk of AF recurrence for each metabolic equivalent (MET) increase in baseline cardiorespiratory fitness. The benefits gained from cardiorespiratory fitness are additive to the effect of weight loss. Increased cardiorespiratory fitness is associated with beneficial effects on blood pressure, diabetic control, lipid profile, and inflammation, all of which can potentially contribute to reduced AF burden. However, guidelines on appropriate weight loss and fitness targets are still lacking.^{61,137,142}

Habitual and binge alcohol drinking increases the risk of new-onset AF as well as the risk of arrhythmia progression in patients with AF. Therefore reducing alcohol consumption can potentially be an effective strategy for primary and secondary AF prevention. In this context, however, a safe level of daily alcohol consumption in AF patients has not been established. In addition, appropriate counseling should be provided for smoking cessation and recreational drug abuse.^{44,89,90}

Management of Postoperative Atrial Fibrillation

Primary Prevention

Multiple strategies for preventing postoperative AF have been studied. Prophylaxis of AF using perioperative beta-blockers, amiodarone, and sotalol has shown promising results. However, no strategy completely eliminates the occurrence of postoperative AF.⁹⁹

Beta-blockers. Oral beta-blockers have been consistently shown to reduce the development of postoperative AF (from 39% to 31%, in one report) and, in the absence of contraindications, are strongly recommended for virtually all patients undergoing cardiac surgery. Generally, oral beta-blocker therapy is started at least 2 to 3 days before surgery, or within 24 hours after surgery if not given preoperatively. The dose is up-titrated as tolerated. In patients already receiving chronic beta-blocker therapy, the drug should be continued without interruption perioperatively.

Amiodarone. Amiodarone reduces the incidence of postoperative AF by more than 50% (compared with placebo); however, its incremental value is less well defined when compared with beta-blocker therapy. Preoperative use of amiodarone to prevent postoperative AF is a class IIa recommendation in the 2014 ACC/AHA/HRS guidelines.⁹⁹

Different regimens of amiodarone have been evaluated. Oral regimens were started at 1, 5, or 7 days before nonemergent surgery and continued for several days postoperatively. IV regimens involve starting amiodarone infusion immediately before or immediately after surgery, which is continued for 48 hours followed by oral therapy for 3 to 4 days. In a recent study, the efficacy of amiodarone in prevention of postoperative AF was maintained irrespective of route (oral vs. IV) and timing of administration (preoperative vs. immediate postoperative), and regardless of the duration of therapy, when at least 300 mg of IV amiodarone was loaded, and a total dose of 1 g was administered.¹⁴³

Sotalol. Sotalol was found to be more effective than beta-blockers for postoperative AF prophylaxis. There was no significant difference in the rates between sotalol and amiodarone. Sotalol therapy is usually started 24 to 48 hours before surgery or four hours after surgery.¹⁴⁴ However, the risk of bradycardia and torsade de pointes, especially in those with electrolyte disturbances, has limited the widespread use of sotalol for the prevention of postoperative AF.⁴⁴

Other therapies. Despite some suggestion of beneficial effects, current evidence does not support the routine prophylactic use of corticosteroids, atrial pacing, posterior pericardiotomy, antioxidant vitamins C and E, n-3 polyunsaturated fatty acids, statins, magnesium, or colchicine to prevent postoperative AF in the cardiac surgical popula-

tion. Studies using verapamil, digoxin, or procainamide showed no significant benefits compared to a placebo.

Perioperative infusion of human natriuretic peptide (carperitide), which inhibits the renin-angiotensin-aldosterone system, was recently shown to reduce the occurrence of postoperative AF in patients undergoing coronary bypass grafting.¹⁴⁵

Of note, prophylactic PV epicardial isolation in patients undergoing coronary bypass grafting does not decrease the incidence of postoperative AF or its clinical impact.⁹⁸

Rate Versus Rhythm Control

Beta-blockers are the drugs of choice for rate control in patients with postoperative AF. The indications for cardioversion of AF and recommendations for rhythm- versus rate-control strategies are similar to those discussed for nonsurgical patients. When antiarrhythmic drug therapy is required for rhythm control, amiodarone is the drug of choice. Sotalol can be considered if amiodarone is contraindicated. Class IC agents, such as flecainide and propafenone, generally are avoided in these patients given the presence of structural heart disease.⁹⁹

Prevention of Systemic Embolization

Guidelines for stroke prevention in nonsurgical AF patients apply to those with postoperative AF. Most of these patients have multiple stroke risk factors but also increased risk of bleeding in the postoperative phase. Therefore the decision to initiate anticoagulation therapy should be guided by the individual patient's bleeding risk and CHA2DS2-VASc score. Data are lacking regarding the threshold burden or duration of postoperative AF at which anticoagulation is favored, but AF lasting for longer than 48 hours should prompt strong consideration of anticoagulation therapy. The optimal duration for which anticoagulation must be continued after cessation of postoperative AF is uncertain.⁹⁹

Follow-Up of Patients With Postoperative Atrial Fibrillation

Follow-up is recommended at 6 to 12 weeks after surgery to evaluate the presence of persistent or paroxysmal AF and reassess management strategy. Ambulatory cardiac monitoring should be considered to screen for asymptomatic paroxysmal arrhythmias. The optimal frequency and intensity of cardiac rhythm monitoring beyond the 3-month period are not known. If AF is documented, long-term anticoagulation should be considered based on the CHA2DS2-VASc score, and the need for rate versus rhythm control should be reassessed. If there is no evidence of symptomatic or asymptomatic AF beyond the immediate postoperative period, discontinuation of antiarrhythmic drug therapy, if initiated after cardiac surgery, is recommended.

ELECTROCARDIOGRAPHIC FEATURES

Atrial Activity

AF is characterized by rapid and irregular atrial fibrillatory waves (f waves) and a lack of clearly defined P waves, with an undulating baseline that can alternate between recognizable atrial activity and a nearly flat line (Fig. 15.12). Atrial fibrillatory activity is generally best seen in lead V₁ and in the inferior leads. Less often, the f waves are most prominent in leads I and aVL.

The rate of the fibrillatory waves is generally between 350 and 600 beats/min. With up to 600 impulses generated every minute, syncytial contraction of the atria is replaced by irregular atrial twitches. Therefore the fibrillating atria look like a bag of worms in that the contractions are very rapid and irregular. The f waves vary in amplitude, morphology, and intervals, thus reflecting the multiple potential types of atrial activation that may be present at the same time at different locations throughout the atria. The f waves can be fine (amplitude less than

Fig. 15.12 Surface Electrocardiogram of Atrial Fibrillation With Chronic Right Bundle Branch Block.

0.5 mm on ECG) or coarse (amplitude more than 0.5 mm). On occasion, the f waves can be inapparent on the standard and precordial leads, which is most likely to occur in permanent AF. It was initially thought that the amplitude of the f waves correlated with increasing atrial size; however, echocardiographic studies have failed to show a correlation among the amplitude of the f waves, the size of the atria, and the type of heart disease. The amplitude, however, may correlate with the duration of AF.

AF should be distinguished from other rhythms in which the R-R intervals are irregularly irregular. These include multifocal AT (see Fig. 15.2), wandering atrial pacemaker, multifocal PACs, and AT or AFL with varying AV block. In general, distinct (although often abnormal and possibly variable) P (or flutter) waves are present during these arrhythmias, in contrast to AF. Patients with rheumatic mitral stenosis often demonstrate large-amplitude fibrillatory waves in the anterior precordial leads (V_1 and V_2), which can be confused with AFL. However, careful examination of the fibrillatory waves reveals them to have a varying CL and morphology. The distinction between AF and AFL can also be confusing in patients who demonstrate a transition between these arrhythmias. Thus AF may organize to AFL or AFL may degenerate to AF (eFig. 15.6). Occasionally, extracardiac artifacts (e.g., 60 cycle/min muscle tremors, as in parkinsonism) can mimic f waves.

Atrioventricular Conduction During Atrial Fibrillation

The ventricular response in AF is typically irregularly irregular, and the ventricular rate depends on multiple factors, including the EP properties of the AVN, the rate and organization of atrial inputs to the AVN, the level of autonomic tone, the effects of medications that act on the AV conduction system, and the presence of preexcitation over an AV BT.

The ventricular rate in untreated patients usually ranges from 90 up to 170 beats/min. Ventricular rates that are clearly outside this range suggest some concurrent influence. Ventricular rates slower than 60 beats/min are seen with AVN disease and can be associated with the

sick sinus syndrome, drugs that affect conduction, and high vagal tone, as can occur in a well-conditioned athlete. The ventricular rate in AF can become rapid (more than 200 beats/min) during exercise, with catecholamine excess (Fig. 15.13), parasympathetic withdrawal, thyrotoxicosis, or preexcitation (Fig. 15.14). The ventricular rate can be very rapid (more than 300 beats/min) in patients with the Wolff-Parkinson-White syndrome, with conduction over AV BTs having short anterograde refractory periods.

The compact AVN is located anteriorly in the triangle of Koch. There are two distinct atrial inputs to the AVN, anteriorly via the interatrial septum and posteriorly via the crista terminalis (see Chapter 9). Experiments in a rabbit AVN preparation demonstrated that propagation of impulses during AF through the AVN to the His bundle (HB) is critically dependent on the relative timing of activation of septal inputs to the AVN at the crista terminalis and interatrial septum. Other investigators showed that the ventricular response also depends on atrial input frequency.

Concealed conduction likely plays the predominant role in determining the ventricular response during AF. The constant bombardment of atrial impulses into the AVN creates substantial and varying degrees of concealed conduction, with atrial impulses that enter the AVN but do not conduct to the ventricle, thus leaving a wake of refractoriness encountered by subsequent impulses. This also accounts for the irregular ventricular response during AF. Although the AVN would be expected to conduct whenever it recovers excitability after the last conducted atrial impulse, which would then be at regular intervals, the ventricular response is irregularly irregular because of the varying depth of penetration of the numerous fibrillatory impulses approaching the AVN, leaving it refractory in the face of subsequent atrial impulses.

Alterations of autonomic tone can have profound effects on AVN conduction. Enhanced parasympathetic and sympathetic tone have negative and positive dromotropic effects, respectively, on AVN conduction and refractoriness. An additional factor is the use of AVN blocking agents such as digoxin, calcium channel blockers, or beta-blockers. There also

may be a circadian rhythm for both AVN refractoriness and concealed conduction that accounts for the circadian variation in ventricular rate.

Ventricular Preexcitation During Atrial Fibrillation

The presence of a grossly irregular, very rapid ventricular response (more than 250 beats/min) with QRS duration longer than 120 milliseconds during AF rarely results from conduction over the AVN and strongly implies conduction over an AV BT (see Fig. 15.14). At very fast heart rates, there is usually a tendency toward regularization of the R-R intervals; therefore distinguishing preexcited AF from VT or pre-excited SVT can be difficult. However, careful measurement always discloses definite irregularities. Moreover, very rapid and irregular VTs are usually unstable and quickly degenerate into VF. Thus, when a rapid, irregular wide QRS complex tachycardia is noted in a patient who has a reasonably stable hemodynamic state, preexcited AF is the most likely diagnosis.

The ability to conduct rapidly over an AV BT is determined primarily by the intrinsic conduction and refractoriness properties of the AV BT. However, as with AVN conduction, factors such as spatial and temporal characteristics of atrial wavefronts during AF, autonomic tone, and concealed conduction influence activation over the AV BT. Very rapid AV conduction during AF can occur in the presence of AV BTs with very short refractoriness, especially when normal conduction through the AVN and HPS is blocked (as occurs with AVN blocking drugs) and ventricular activation occurs only via the rapidly conducting BT, which would then eliminate retrograde concealment into the BT. This would

result in extremely rapid ventricular rates, possibly more than 300 beats/min, which can occasionally degenerate into VF.

Regular Ventricular Rate During Atrial Fibrillation

Regular ventricular rate during AF indicates associated abnormalities. A regular, slow ventricular rhythm during AF suggests a junctional or ventricular rhythm, either as an escape mechanism with complete AV block or as an accelerated pacemaker activity with AV dissociation (see Fig. 9.27). Rarely, the R-R interval can be regularly irregular and show group beating with the combination of complete heart block and a lower nodal pacemaker with a Wenckebach type of exit block. Patients with severe underlying heart disease may develop the combination of AF and VT, leading to a rapid, regular, wide QRS complex tachycardia.

Effect of Digitalis Toxicity on the Ventricular Response

With increasing degrees of digitalis toxicity, high-grade but not complete AV block during AF initially leads to single junctional or ventricular escape beats. Higher degrees of AV block result in such a small number of atrial impulses being conducted that the lower pacemaker takes over, thus leading to an escape junctional or ventricular rhythm with a regular R-R interval for two or more cycles. On occasion, the junctional rate can increase, possibly because of digitalis-induced triggered activity, and it is called nonparoxysmal junctional tachycardia. Increasing digitalis toxicity can result in a Wenckebach exit block and give the appearance of an irregular ventricular rhythm with restoration of AF conduction,

Fig. 15.14 Preexcited Atrial Fibrillation (AF). (A) Electrocardiogram (ECG) showing normal sinus rhythm (NSR) with a Wolff-Parkinson-White pattern and preexcitation using a left lateral bypass tract (BT). (B) ECG showing preexcited AF (i.e., AF with conduction over the BT).

but the rhythm shows repetitive group beating because of the exit block. Complete AV block is marked by a regular escape rhythm with no conducted beats, a finding that may lead to the erroneous assumption that the patient has converted to NSR. Infrequently, impulses from the lower pacemaker travel alternately down the right and left bundle branches or alternate fascicles of the left bundle branch, resulting in a

bidirectional tachycardia. This arrhythmia, which is also frequently a reflection of marked digitalis toxicity, may appear to be ventricular bigeminy. In true bigeminy, however, the ventricular beat in the bigeminal pattern is premature. In comparison, the R-R interval is regular with a bidirectional tachycardia because all the beats arise from a single pacemaker.

QRS Morphology

The QRS complexes during AF are narrow and normal unless AV conduction is abnormal because of functional (rate-related) aberration, preexisting bundle branch block (BBB) (see Fig. 15.12), or preexcitation over an AV BT (see Fig. 15.14).

Aberrant conduction commonly occurs during AF. Aberrancy is caused by the physiological changes of the conduction system refractory periods that are associated with sudden changes in heart rate. The refractoriness of the HPS tissue is directly related to the preceding R-R interval. Thus there can be aberrant conduction from a long R-R interval followed by a short cycle. In this scenario, the refractory period of the bundles increases during the long R-R interval (long cycle). The QRS complex that ends the long pause will be conducted normally but is followed by a prolonged refractory period of the bundle branches. If the next QRS complex occurs after a short coupling interval, it can be conducted aberrantly because one of the bundle branches is still refractory due to a lengthening of the refractory period (the Ashman phenomenon). The gross irregularity of the ventricular response during AF yields an abundance of different R-R intervals; therefore the long-short cycle sequence occurs commonly, and the Ashman phenomenon is seen frequently during AF; right bundle branch block (RBBB) aberrancy is more common than left bundle branch block (LBBB) aberrancy, because the right bundle branch has a longer refractory period at slower heart rates. The left anterior fascicle is also frequently involved, often in combination with RBBB. In contrast, functional aberration is uncommon in the HB, the left posterior fascicle, or the main left bundle. Moreover, CLs preceding the pause may also affect the chance for aberrancy after the pause.

The aberrancy caused by the Ashman phenomenon can be present for one beat and have a morphology that resembles a PVC, or it can

involve several sequential complexes, suggesting VT. The persistence of aberrancy may reflect a time-dependent adjustment of refractoriness of the bundle branch to an abrupt change in CL, or it can potentially be the result of concealed transseptal activation.

Although functional BBB is common in AF, PVCs are even more frequent, and it is important to differentiate between aberrant ventricular conduction and VT when repetitive wide QRS complexes occur during AF. The presence or absence of a long-short cycle sequence may not be helpful in differentiating aberration from ectopy for two reasons. Although a long cycle (pause) sets the stage for the Ashman phenomenon, it also tends to precipitate ventricular ectopy. Moreover, concealed conduction occurs frequently during AF, and therefore it is never possible to determine exactly when a bundle branch is activated from the surface ECG.

The proper diagnosis of aberrant conduction is a continuing challenge, but it can usually be accomplished by careful analysis of the rhythm strip and application of certain criteria. An aberrantly conducted beat caused by functional BBB generally has the pattern of a classic bundle branch or fascicular block. A PVC is usually followed by a longer R-R cycle, indicating the occurrence of a compensatory pause, the result of retrograde conduction into the AVN and anterograde block of the impulse originating in the atrium. The presence of long R-R cycles after the wide QRS complex that have identical CLs also suggests a ventricular origin (see eFig. 10.2). Furthermore, the absence of a long-short cycle sequence associated with the wide or aberrant QRS complex suggests that it is of ventricular origin. Aberrancy is likely not present if, with inspection of a long ECG rhythm strip, there are R-R interval combinations that are longer and shorter than those associated with the wide QRS complex. Also, a ventricular origin is likely if there is a fixed coupling interval between the normal and wide QRS complexes (Fig. 15.15).

Fig. 15.15 Surface Electrocardiogram of Atrial Fibrillation (AF) With Right Bundle Branch Block and Premature Ventricular Complexes (PVCs). Ventricular bigeminy is present. Note the fixed coupling interval of the PVCs. Also, QRS morphology during PVCs is different from that during conducted AF complexes and is inconsistent with aberration.

CATHETER ABLATION OF ATRIAL FIBRILLATION

Evolution of Catheter Ablation Approaches for Atrial Fibrillation

Catheter Ablation of Atrial Fibrillation: Elimination of Triggers

Focal ablation of triggers. The landmark publication of Haïssaguerre and colleagues in 1998 demonstrated that paroxysmal episodes of AF are consistently initiated by spontaneous triggers or atrial extrasystoles. Remarkably, 94% of those triggers originated from the sleeves of LA muscle investing the PVs. Spontaneous reinitiation of AF could be eliminated by focal ablation at the site of origin of the trigger. The initial technique was to identify and ablate the culprit focus within the PV, but this approach was limited by the complication of PV stenosis and the recognition that multiple PVs were involved in most patients, which led to frequent recurrences after a “successful” procedure. Moreover, it is frequently difficult to elicit PV arrhythmia in the EP laboratory to allow adequate mapping and ablation.

PV isolation. Recognition of major limitations of focal ablation has led to the development of the PV electrical isolation technique. Recognizing that PV musculature conducts to LA musculature by discrete connections has allowed investigators to target those connections using multipolar catheters shaped into rings or baskets. Ablation is performed with a separate roving catheter at the site of earliest activation sequentially until PV electrical activity disappears or becomes dissociated from the LA activity (Fig. 15.16). Using this strategy, between 20% and 60% of the PV circumference is targeted by ablation. PV isolation has the additional advantage of simultaneously treating all triggering foci within the vein, thereby obviating the need to elicit and map those foci individually. For the same reason, investigators were soon led to attempt to isolate as many PVs as possible at the initial ablation session. Comparative case series ultimately demonstrated that empirical isolation of the four PVs led to superior outcomes over isolating fewer veins.

It was subsequently found that the incidence of PV stenosis could be reduced significantly by ablating just outside the PV ostia (i.e., on the atrial aspect). Using this approach, ablation is performed circumferentially around the antrum of each of the four PVs (see Fig. 15.16). In addition to elimination of PV triggers, circumferential antral PV isolation was found to modify potentially important elements of the AF substrate, which commonly localize to the antral regions of the PV (e.g., rotors and ganglionated plexuses). Furthermore, the circumferential ablation lines incorporate a large area of the posterior LA, contributing to atrial debulking.

With further research, it was also observed that non-PV foci were an important source of AF in some patients, although percentages varied among different groups. Among the sources identified are the vein of Marshall, the CS, and the SVC, all of which are, like the PVs, thoracic veins. Targeting those triggers by either focal ablation or electrical isolation of the involved thoracic veins has been attempted in selected patients.

Catheter Ablation of Atrial Fibrillation: Substrate Modification

Cox and colleagues developed a series of techniques for the surgical disruption of AF. The final iteration, the maze III procedure, was based on a model of AF in which maintenance of the arrhythmia requires persistence of a critical number of circulating wavelets of reentry, each of which requires a critical mass of atrial tissue to sustain it. The concept behind the maze III, in which a series of complete, transmural incisions are made in the left and right atria, was that by dividing the atria into small enough electrically isolated compartments, reentrant activity was

Fig. 15.16 Catheter Ablation of Atrial Fibrillation (AF). Atrial anatomy is shown at top; both atria are opened and viewed from the front. Various procedures for catheter ablation of AF are shown (red dots are ablation lesions). See text for further discussion. LA, Left atrium; PV, pulmonary vein.

no longer possible and maintenance of AF could be prevented, regardless of the mode of initiation. However, application of the maze III operation has been limited by the morbidity and risk associated with sternotomy-thoracotomy and cardiopulmonary bypass, as well as by the limited adoption by cardiothoracic surgeons. With the success of the Cox-maze procedure, multiple variations of the procedure have been performed, most of which have involved the use of a smaller lesion set. The LA lesion set was found to be fairly adequate to prevent AF, whereas RA lesions were required to prevent the development of AFL. Isolation of the PVs and posterior LA was a feature common to all successful iterations of the maze procedure. Therefore this and other similar compartmentalization procedures have evolved over time and now predominantly involve the LA. In general, all these approaches have lower success rates than the maze III procedure.

The success of surgical linear lesions led to the development of the catheter-based approach to perform linear ablation. Initial attempts at delivering long lines of RF ablation aimed at mimicking the lines of the surgical maze. Schwartz and associates reported recreation of the maze III lesion set in a small series of patients by using specially designed sheaths and standard RF catheters. Although the efficacy was modest, complication rates were high, and procedure and fluoroscopy times were exceedingly long, this report demonstrated a proof of concept that led others to try to improve the catheter-based approach. Further refinement of the linear catheter ablation technique involved creating a series of ablation lesions using RF catheters to create specific lesion

sets in the RA (two lines) and LA (three or four lines). The RA lesion sets consisted of an intercaval line along the interatrial septum and a cavotricuspid isthmus (CTI) line to prevent AFL. LA lesions were designed to connect the four PVs to each other and to the mitral annulus. As increasing evidence emerged regarding the importance of the LA in the maintenance of AF, ablation targets became limited to the LA.

In the late 1990s, Pappone and coworkers developed the wide-area circumferential ablation approach using three-dimensional (3-D) electroanatomic mapping. RF ablation was performed circumferentially around ipsilateral PVs, with the endpoint of ablation being the absence or marked reduction in the amplitude of electrical signals within the encircling lesions (see Fig. 15.16). Despite lack of evidence showing that PVs treated in this way are electrically isolated from the LA, this group began reporting results for paroxysmal AF which were just as good as or better than those working with the ostial segmental PV isolation approach. Furthermore, patients with persistent or permanent AF treated with the Pappone approach achieved freedom from AF almost as good as in patients with paroxysmal AF and far better than reports of patients treated with segmental PV isolation. Further iterations have required a strategy closer to the surgical maze—that is, lines to connect the ipsilateral pairs of the PVs and a line to link the left PV encircling lesion to the mitral annulus, which can be described as the *catheter maze*. Such lines further improved the outcomes of paroxysmal AF and have produced good results for ablation of longstanding persistent AF as well. It became clear that producing lines with proven transmural conduction block leads to a lower rate of recurrence of AF. However, achieving this is technically challenging and requires long, arduous procedures. Also, gaps in these lines could promote macroreentrant AT.

Later on, several other ablation strategies were developed aiming to modify potential substrates that underlie the sustenance of AF. These include ablation of atrial sites exhibiting complex fractionated electrograms reflecting regions with slow conduction, which were thought to be critical for maintaining AF. In addition, neuromodulation has been attempted by selective ablation of LA ganglionated plexuses (see Fig. 15.16). More recently, the localized source hypothesis as the underlying mechanism for AF has received close attention (see above). Studies employing panoramic atrial mapping during AF have used phase analysis of contact atrial endocardial electrograms from basket electrode catheters (FIRM) or reconstructed atrial electrograms from body surface recordings (ECG imaging) to identify regions of recurrent organized rotational activity (rotors) and focal sources (focal drivers) within the atria, which can potentially have a mechanistic role in sustaining AF, and design tailored ablation strategies that selectively targeted those sources. In addition, new, patient-tailored substrate modification strategies have been used targeting fibrotic atrial regions identified by voltage mapping or CMR.

At this time circumferential PV isolation remains the “gold standard” and the recommended approach for catheter ablation of AF. However, its success rate remains suboptimal especially in patients with persistent AF in whom a variety of additional ablation techniques have been proposed to improve procedural outcome. In general, substrate-based ablation techniques are used in conjunction with circumferential antral PV isolation; their use as a stand-alone procedure for either paroxysmal or persistent AF without any attempt to isolate the PVs electrically has been associated with high rates of arrhythmia recurrence, and this approach has been largely abandoned.¹⁴⁶

Periprocedural Management

Antiarrhythmic Drug Therapy

Antiarrhythmic medications are frequently stopped more than five half-lives before the ablation procedure because they can suppress spontaneous firing and fractionation of the electrograms that can be used to

guide ablation. However, a longer period (approximately 6 months) is required for amiodarone, which may not be practical. Hence, amiodarone may be continued or discontinued before or after ablation.

In patients with persistent AF, it may be reasonable to attempt electrical cardioversion and maintenance of NSR using antiarrhythmic medications as a prelude to ablation. Restoration of NSR, even for a relatively short time, can potentially result in reverse electrical atrial remodeling and improve the outcome of the ablation procedure.

Continuing antiarrhythmic drug therapy after ablation can potentially reduce the incidence of early recurrences of symptomatic atrial arrhythmias and the need for cardioversion or hospitalization for arrhythmia management. However, this strategy does not seem to improve long-term freedom from AF. Also, antiarrhythmic treatment can be initiated in select patients, such as those with incomplete or unsuccessful ablation procedures and patients with early recurrences of AF or AFL after ablation.^{147,148}

In patients discharged with antiarrhythmic drug therapy, such therapy is usually discontinued after 1 to 3 months if no recurrence of AF is observed. In patients discharged without antiarrhythmic drug therapy who develop recurrent AF, antiarrhythmic drug therapy is initiated unless the patient is satisfied with the extent of symptomatic improvement or elects to undergo a repeat ablation procedure.¹⁴⁸

Of note, a recent study found that, in patients free of AF at the end of 3 months following catheter ablation, continued use of previously ineffective antiarrhythmic drug therapy was associated with a lower rate of recurrences of atrial tachyarrhythmias and repeat ablation, without compromising the quality of life. This hybrid rhythm control approach can be a reasonable strategy in select AF patients.

Periprocedural Anticoagulation

Catheter ablation of AF is associated with significant risk of thromboembolism during and for several weeks following the procedure. The transiently heightened prothrombotic state associated with AF ablation is observed even in patients who were identified as low-risk before ablation. Ablation-related thromboembolism can be attributed to thrombus formation on the LA catheters and sheaths, char formation at the tip of the ablation catheter or at the site of ablation, development of LA thrombi due to stunned atrial tissue after conversion of AF to NSR, or thrombus formation over the disrupted endothelium from the ablation lesions. On the other hand, anticoagulation can increase the risk of hemorrhagic complications, including hemopericardium, pericardial tamponade, and vascular complications. Therefore rigorous periprocedural anticoagulation is of paramount importance to prevent thromboembolic events while minimizing hemorrhagic complications.

Preprocedural anticoagulation. Patients undergoing catheter ablation of AF are anticoagulated with warfarin (INR 2.0 to 3.0) or a NOAC for more than 3 to 4 weeks before the procedure. Two strategies of periprocedural anticoagulation have been used. The first strategy involves interruption of oral anticoagulation before the procedure and bridging with enoxaparin or IV heparin. With this strategy, oral anticoagulation is usually stopped (2 to 5 days for warfarin, and 1 to 2 days for NOACs) before the procedure, and replaced with enoxaparin or IV heparin once oral anticoagulation levels become subtherapeutic (i.e., when INR becomes less than 2.0 or when the next NOAC dose is due). Enoxaparin is stopped 12 to 24 hours and heparin is stopped 4 to 6 hours before ablation, and then restarted after ablation 4 to 6 hours after vascular hemostasis is successfully achieved, and continued until therapeutic levels of oral anticoagulation (INR 2.0 to 3.0) are reached. This approach, however, not only is impractical and cumbersome, but also exposes the patient to inadequate anticoagulation in the immediate postablation period, when anticoagulation is especially important given the heightened risk of cardiac thromboembolism due to tissue inflammation and

endothelial damage inherently associated with ablation. In addition, the use of enoxaparin or IV heparin is associated with high risk of vascular access complications.

An alternative strategy that is being used more frequently is the continuation of periprocedural oral anticoagulation without the use of heparin or enoxaparin for bridging. With this strategy, oral anticoagulation (with warfarin at a therapeutic INR) is continued at the time of ablation. This approach was found superior to the interrupted warfarin strategy and heparin bridging in terms of both the efficacy (lower risk of periprocedural thromboembolism) and safety (lower risk of bleeding) and, hence, has become the preferred anticoagulation approach in AF patients undergoing catheter ablation. Uninterrupted anticoagulation strategies eliminate a period of inadequate anticoagulation immediately following the ablation procedure, and it potentially reduces the risk of acute bleeding complications by obviating the need for heparin or enoxaparin therapy after ablation.¹⁴⁹ Similar data are emerging for NOACs; several recent studies found that uninterrupted administration of NOACs (with or without holding one or two doses of the NOAC in the day prior to the procedure) did not differ significantly from interrupted or continuous warfarin treatment with regard to the incidence of periprocedural thromboembolism, and may be associated with a lower risk of bleeding complications during the periprocedural period.^{150,151}

Intraprocedural anticoagulation. Intraprocedural anticoagulation with IV heparin is administered to all patients, even those with therapeutic levels of oral anticoagulation at the time of the procedure. During the initial experience with AF ablation, anticoagulation with heparin was delayed until after the LA access had been achieved because of fear of complications with the transseptal puncture. Later, it became evident that such a strategy can allow thrombus formation on sheaths, catheters, and high-profile wires in the RA before transseptal puncture, and these thrombi could potentially travel to the LA. In addition, recent evidence suggests that unfractionated heparin displays unexpected slow anticoagulation kinetics in a significant proportion of patients for up to 20 minutes after infusion. Hence, many operators now favor complete heparinization after vascular access, and clearly before transseptal puncture.^{152,153}

Initially, a loading dose of IV heparin is administered, followed by intermittent boluses or continuous infusion; heparin infusion can potentially prevent wide fluctuation of activated clotting time (ACT) levels, especially during long procedures. The ACT should be checked at 10- to 15-minute intervals until therapeutic anticoagulation is achieved, and then at 15- to 30-minute intervals for the duration of the procedure. Heparin dose is adjusted to achieve a target ACT of 300 to 350 seconds, even when using an uninterrupted oral anticoagulation strategy. Studies have shown that an ACT below 300 seconds during the procedure, and failure to administer IV heparin bolus before transseptal catheterization, are related to major thromboembolic complications.

Of note, patients receiving uninterrupted periprocedural warfarin therapy appear to require lower doses of heparin and reach the target ACT (greater than or equal to 300 seconds) faster as compared to patients with subtherapeutic INRs. In contrast, in patients on uninterrupted NOAC therapy, achieving the target ACT often is more delayed and requires larger doses of IV heparin. Therefore more frequent ACT monitoring and higher heparin doses should be used in the latter group of patients. A recent report proposed an individualized heparin dosing regimen: an initial heparin bolus of 50 units/kg in patients who are therapeutically anticoagulated with warfarin, 75 units/kg in patients who are not anticoagulated prior to ablation, and 120 units/kg for patients who are anticoagulated on a NOAC and have held one to two doses.¹⁵⁴

At the conclusion of the ablation procedure, sheath removal requires interruption of anticoagulation to achieve adequate hemostasis. Heparin

infusion can be discontinued and the sheaths removed when the ACT is less than 200 seconds. Alternatively, protamine can be administered to reverse heparin effects (1 mg of protamine for every 100 units of heparin received in the previous 2 hours). Hemostasis can be achieved by either direct pressure or the use of a figure-of-8 suture.

Postprocedural anticoagulation. Oral anticoagulation is restarted as soon as possible after the procedure, provided there is no evidence of ongoing bleeding or a significant pericardial effusion. In patients treated with NOACs, the NOAC is restarted 3 to 5 hours after completion of the procedure and removal of the vascular sheaths. For patients on uninterrupted warfarin therapy with therapeutic INR, warfarin daily regimen is resumed postablation. In patients with subtherapeutic INR the day of the procedure, bridging with enoxaparin or IV heparin is recommended until a therapeutic INR is achieved; however, substituting warfarin with a NOAC postablation is a preferred strategy and can potentially reduce the risk of bleeding associated with heparin or enoxaparin bridging.

Oral anticoagulation is continued for a minimum of 2 to 3 months after ablation in all patients, regardless of the CHA2DS2-VASc score or rhythm status. Decisions regarding the use of oral anticoagulation for more extended periods should be based on the patient's stroke risk profile (CHA2DS2-VASc score) and according to the guidelines for other patients with AF, and not on the perceived success or failure of the ablation procedure. Anticoagulation can be discontinued in patients with low stroke risk (CHA2DS2-VASc 0 in men or 1 in women), unless cardioversion is anticipated or has recently been performed. On the other hand, long-term anticoagulation is recommended for patients with a CHA2DS2-VASc score of 2 in men or 3 in women. Although some reports showed that discontinuation of anticoagulation therapy 3 months after successful catheter ablation can be safe over medium-term follow-up in some subsets of patients, this has not been confirmed by a large prospective randomized trial and therefore remains unproven. There is far greater flexibility as to how anticoagulation is managed in patients at an intermediate risk of stroke (CHA2DS2-VASc of 1 in men or 2 in women).

When discontinuation of oral anticoagulation therapy is being considered (based on the preference of a well-informed patient) following an apparently successful ablation procedure in a patient with a high risk of stroke, recurrences of AF should be excluded with confidence, which requires extended periods of continuous cardiac monitoring (see below). Reliance only on symptoms as an indicator for AF recurrence or event-triggered ambulatory monitoring can be misleading and can underestimate the incidence of recurrence. In addition, these patients should consider undergoing continuous or frequent ECG monitoring at regular intervals to screen for silent AF as long as they remain untreated with systemic anticoagulation.

Of note, some data have shown a temporal dissociation of actual AF episodes and thromboembolic events, suggesting presence of an underlying atrioopathy that results independently in both AF and thromboembolic risk. In such cases, elimination of AF may not impact thromboembolic risk.

Transesophageal Echocardiography

TEE is performed in most patients undergoing AF ablation to screen for LA thrombus. Although it is optional in patients with paroxysmal AF and no structural heart disease, preablation TEE is often performed in patients who are in AF at the time of the procedure, regardless of the anticoagulation status prior to ablation. The presence of intracardiac thrombus should prompt cancellation of the procedure and mandate 4 to 8 more weeks of anticoagulation, followed by another TEE.

Some reports suggested that a TEE may not be necessary in patients receiving uninterrupted oral anticoagulation therapy for 4 weeks

Fig. 15.17 Intracardiac Echocardiography (ICE) of the Left Atrial Appendage (LAA). (A) Segmented three-dimensional cardiac computed tomography (in the left anterior oblique [LAO] projection) showing the anatomic relationship between the LAA and pulmonary artery (PA). (B) Fluoroscopic view (LAO) of the ICE transducer positioned in the PA for imaging of the LAA. The ablation catheter (*Abl*) is positioned in the LAA. (C) ICE image of the LAA (*arrowheads*) acquired with the ICE transducer position in the PA. CS, Coronary sinus; LCA, left coronary artery.

preceding the ablation and through the day of the procedure. However, other studies reported a substantial prevalence of LAA clots among patients with full anticoagulation and in those with paroxysmal AF (up to 6.4% in those with high CHA2DS2-VASc score), and suggested that TEE should be performed in all patients prior to ablation. Therefore until more data are available, the risk of a thromboembolic event must be weighed against relatively low risk of moderate sedation and TEE, by taking into consideration the type of AF (paroxysmal vs. persistent), anticoagulation status, CHA2DS2-VASc score, LA diameter, and LV function. At this time, it may be reasonable to perform TEE in all patients, with the possible exception of those with paroxysmal AF and a CHA2DS2-VASc score of 0.^{1,155,156}

The technique of 64-slice computed tomography (CT) scanning has been used to screen for atrial thrombi with reportedly high diagnostic accuracy, but TEE remains the gold standard and the preferred imaging modality. In addition, the use of intraprocedural intracardiac echocardiography (ICE) may be considered for screening of LAA thrombi (imaging from the pulmonary artery is preferred, Fig. 15.17) in patients who cannot undergo TEE; however, the data are currently insufficient to recommend widespread use of ICE imaging as an alternative to TEE (eFig. 15.7).

Postprocedural Electrocardiogram Monitoring

Patients are generally hospitalized the night after the procedure, with cardiac monitoring, and discharged home the following day. After hospital discharge, the method and frequency of cardiac monitoring depends on individual needs and the consequences of arrhythmia detection.

Patients who report symptoms compatible with an arrhythmia should undergo ambulatory cardiac monitoring, which (depending on the frequency of symptoms) may include 12-lead ECGs, Holter monitors, patient-activated event recorders, and automatically activated external loop recorders.

On the other hand, arrhythmia monitoring to assess the efficacy of the ablation procedure is typically delayed for at least 3 months following ablation because early recurrences of atrial arrhythmias are common during the first 1 to 3 months after ablation and many of them resolve spontaneously. Importantly, the disappearance of arrhythmia symptoms postablation should not be equated with absence of AF.

In fact, the proportion of asymptomatic compared with symptomatic arrhythmia events in AF patients often increases after ablation. Therefore long-term cardiac ambulatory monitors to screen for asymptomatic occurrences of atrial arrhythmias need to be considered. Mobile cardiac telemetry devices are often used, and they provide continuous monitoring for a period of 2 to 4 weeks with real-time AF detection. Since the rate of detection of AF on cardiac monitoring is directly related to the duration and frequency of monitoring, continuous monitoring over extended periods is recommended when detection of asymptomatic AF would influence decision making regarding anticoagulant therapy after ablation. While periodic monitoring with mobile cardiac telemetry devices if often employed, implanted loop recorders (for continuous long-term surveillance) and smartphone-based ECG monitors (for intermittent long-term surveillance) can be considered to improve patient's compliance.¹

Pulmonary Vein Imaging

CMR or contrast-enhanced, multislice CT scanning of the LA with 3-D reconstruction is performed to define the anatomy of the PVs before the procedure (see Fig. 15.6). After ablation, CT or CMR is important to evaluate for evidence of PV stenosis in patients in whom there is a clinical suspicion. Although some investigators recommend routine follow-up imaging for detection of asymptomatic PV stenosis 3 to 4 months after ablation of AF, it is unknown whether early diagnosis and treatment of asymptomatic PV stenosis provide any long-term advantage to the patient. Nevertheless, follow-up PV imaging should be considered during the initial experience of a new AF ablation procedure for quality assurance.

Technical Aspects Common to Different Methods of Ablation

Sedation During Ablation

In most patients, deep sedation or general anesthesia is used to prevent patient movements during long and potentially painful procedures and improve catheter and mapping system stability. Conscious sedation is used less frequently; the choice often is determined by the institutional preference and also by assessment of the patient's suitability for conscious sedation. Advantages of general anesthesia include optimal airway

eFig. 15.7 Intracardiac Echocardiography (ICE) of Left Atrial Appendage (LAA) Thrombus (*Arrow*). In A, the ICE transducer is positioned at the tricuspid annulus. In B, the ICE transducer is positioned in the pulmonary artery (PA). LA, Left atrium; LV, left ventricle.

management, pain control, patient immobilization, as well as enhanced tolerance of esophageal temperature probes. Furthermore, phrenic nerve stimulation, if performed, can cause significant movement in nonanesthetized patients.

Left Atrial Access

Mapping and ablation in the LA are performed through a transseptal approach (see detailed discussion in **Chapter 4**). Even if a patent foramen ovale exists, some operators prefer septal puncture to access the LA since the foramen ovale is typically higher on the septum than might afford optimal reach to all LA locations. Generally, one or two transseptal punctures are performed, and one or two long vascular sheaths are introduced into the LA. The long sheaths are flushed with heparinized saline at a low infusion rate during the entire procedure, whether or not they are withdrawn into the RA during the LA mapping and ablation portion of the procedure.

For ablation strategies utilizing a multielectrode catheter for LA-PV mapping (in addition to the ablation catheter) using two transseptal accesses, one for each catheter is preferred to using a single transseptal access and exchanging diagnostic and ablation catheters over the transseptal sheath. The latter technique can potentially increase the risk for embolic events due to manipulation of the sheath introducing air or thrombi.

Identification of the Pulmonary Veins

Initial approaches of focal ablation targeting arrhythmic foci within the PVs were associated with high incidences of PV stenosis. To avoid this serious complication, the ablation procedure has evolved over time to an increasingly proximal ablation, first at the venous ostium or venoatrial junction and most recently proximal to the PV to encompass the antral region. However, the more proximal ablation approaches require correct identification of the ostia and PV-LA junction, and given the marked variation in PV anatomy, assessment of the number of PVs and anatomy of the ostia is essential when planning an ablation strategy. Various imaging techniques have been developed in an attempt to identify the PV ostium more accurately, but exact localization of this structure remains difficult, and the exact definition of the PV ostium varies, depending on the imaging modality used. Ultimately, however, the choice of imaging modality is dictated by local availability.

Fluoroscopy. Entry into the PV is clearly identified as the catheter leaves the cardiac shadow on fluoroscopy and electrical activity disappears; however, the ostium is located more proximally. The inferior portion of the PV ostia can be localized by advancing the catheter into the PV with downward deflection of the tip and then dragging back while fluoroscopically monitoring the drop off the ostial edge of the catheter.

Intracardiac echocardiography. Phased-array ICE can be used to visualize the antrum and ostium of the PVs (see detailed discussion in **Chapter 6**). ICE has the advantage of providing real-time imaging of the PVs. In contrast to angiography, ICE can define the proximal edge of the PV antrum (see **Fig. 6.32**).

Electroanatomic mapping. Electroanatomic mapping systems (CARTO, Biosense Webster, Diamond Bar, CA, United States; EnSite NavX, St. Jude Medical, St. Paul, MN, United States; or Rhythmia, Boston Scientific, San Jose, CA, United States) have been used to construct a 3-D shell of the LA and identify the PVs.

Combining electroanatomic mapping systems with cardiac imaging. Cardiac CT and CMR provide critical information regarding the number, location, and size of the PVs, which is needed in planning the ablation and selecting appropriately sized mapping and ablation devices. In addition, preacquired CMR and CT scans have the advantage of allowing full integration with 3-D mapping systems and real-time

catheter navigation on a 3-D CT or CMR image, which can facilitate identification of PV ostia and ablation targets (see detailed discussion in **Chapter 6**).

PV angiography. PV angiography can be used at the time of catheter ablation to detail PV anatomy. Selective PV angiography is performed using a 5- to 10-mL hand injection of contrast medium through a long sheath (for angiography of right superior, left superior, and left inferior PVs) or NIH catheter (for angiography of right inferior PV; **eFig. 15.8**). A limitation of the selective PV venography approach is that noncatheterized PVs can be missed if a preacquired CT or CMR is not available to ensure that all the PVs are identified. Alternatively, PV angiography is performed by injecting contrast in the left and right pulmonary arteries or the pulmonary trunk; PVs are then assessed during the venous phase of pulmonary arteriography. A third technique used for PV angiography involves contrast injection in the body of the LA or at the roof of the right or left superior PV ostium immediately after administration of an adenosine IV bolus to induce AV block; the contrast medium will fill the LA body, PV antrum, and proximal part of the PV during the phase of ventricular asystole.

An important limitation of PV angiography is that it images only the tubular portion and does not adequately define the full posterior extension of the PV. Studies of PV anatomy from pathological specimens and 3-D CT scans have shown that the PV is funnel-shaped, with a tube that fans out into a proximal cup that blends into the posterior atrial wall, referred to as the antrum. Furthermore, the PV antrum connects to the LA wall at an oblique angle. The posterior aspect of each PV is more proximal, whereas the anterior segments of the PVs are more distal.

Catheterization of the Pulmonary Veins

In the anteroposterior fluoroscopic view, the PV ostia are situated on both sides of the spine. Clockwise rotation of the catheter inside the LA directs its tip posteriorly and toward the PVs. It is frequently necessary to apply clockwise torque to both the catheter and its long sheath.

For catheterization of the left PVs, the catheter should be directed anteroposteriorly in the right anterior oblique (RAO) fluoroscopic view and to the left in the left anterior oblique (LAO) view. Care must be taken to avoid advancing the catheter into the LAA, in which case the catheter is directed anteriorly (to the right in the RAO view) and not anteroposteriorly. Advancing a catheter into the LAA results in an increase in electrogram amplitude, rather than decreasing amplitude, when advancing into a PV.

For catheterization of the right PVs, the catheter is rotated further clockwise and is directed to the right in the RAO view and anteroposteriorly in the LAO view. An alternative method for reaching the ostia of the right PVs is to loop the catheter around the lateral, inferior, and then septal LA walls, laying the catheter down along the wall, and dragging the catheter by withdrawing it along the posterior right ostia. Forming a tight loop with maximal deflection of the catheter and using rotational movements can provide greater stability during ablation, particularly at the anterior aspect of the PVs.

Counterclockwise rotation of the catheter inside the LA would lead the catheter into the LV. Care must be taken not to allow the circular (Lasso) catheter to cross the mitral annulus because it can then become trapped with the mitral valve apparatus. Usually, reversal of the catheter movement (clockwise torque) that resulted in this situation helps correct it. Also, advancing the sheath over the shaft of the catheter (into the LV) and pushing forward, to free the catheter tip from entanglement, is usually successful.

The use of transseptal steerable sheaths can improve catheter stability and tissue contact and facilitate access to more distant parts of the LA, especially in patients with severe LA dilatation.

FOCAL ABLATION OF PULMONARY VEIN TRIGGERS

Rationale

There are two different types of arrhythmias that can play a role in generating AF, and both can be addressed by focal ablation. One type is a PAC (or runs of PACs) that triggers self-sustained AF (focal triggers). Ablation of a focal trigger does not terminate AF but prevents its reinitiation (see Fig. 15.2). A second type is a focal tachycardia that either induces fibrillation in the atria or mimics AF by creating a pattern of rapid and irregular depolarization wavefronts in the atria. Such a tachycardia acts as a focal driver and is necessary for the continuation and maintenance of AF. Ablation of a focal driver results in the termination of AF and prevention of its reinitiation. Focal tachycardias that initiate or mimic AF can be recognized in the EP laboratory because they are frequently associated with exit block between the site of origin of the tachycardia and the rest of the atria (Fig. 15.18).

Several observations have provided evidence that the electrical activity that arises in the PVs plays a role in the maintenance of AF. By analyzing surface ECG and 24-hour Holter recordings, studies have shown that most paroxysmal AF episodes are initiated by a single PAC. Although focal sources of AF can be found in the RA, LA, CS, SVC, or vein of Marshall, most foci are located within a PV. It is possible that intermittent bursts of PV tachycardia serve to perpetuate AF in the same fashion as bursts of rapid atrial pacing (see Fig. 15.18).

There can be a subset of patients with focally induced AF in whom ablation of a single dominant focus can result in cure, without the need for empirical isolation of all PVs. A more limited ablation approach requires shorter procedure and fluoroscopy times and can be safer. These are important considerations in a relatively young patient population. However, if other PVs or sources are dormant at the time of the procedure but become active subsequently, the patient may experience more AF episodes.

Identification of Arrhythmogenic Pulmonary Veins

Definition of an Arrhythmogenic Pulmonary Vein

An arrhythmogenic PV is defined by single or multiple ectopic discharges originating from the vein, with or without conduction to the LA. During ectopy from an arrhythmogenic PV, there is a reversal in activation sequence, from the distal PV trunk (source) to the ostium and LA (exit), with the PV potential preceding the LA potential (eFig. 15.9; Fig. 15.19). Conversely, if the explored PV is not the origin of ectopy, it is passively activated, as in NSR, with a proximal-to-distal sequence and a PV potential after or fusing with the LA potential.

Ectopic discharges with a short coupling interval may not be conducted to the LA, thus producing isolated PV potentials confined within the PV. These can be recognized as a PV potential coincident with or just after the ventricular electrogram and can be distinguished from a potential of ventricular origin by their spontaneous disappearance (intermittent PV potential) or suppression during atrial pacing (Fig. 15.20).

During an episode of AF, rapid rhythms arising in the PVs (variably referred to as rapid focal activity, repetitive rapid activity, intermittent PV tachycardia, or paroxysmal CL shortening) are common and can play an important role in the maintenance of AF or can be markers of an arrhythmogenic PV that triggers AF during NSR. The CL of local activity within the arrhythmogenic PV is shorter than that of the atrium. In contrast, the local CL in passively activated PVs is similar to or longer than that of the atrium (see Fig. 15.18).

Provocation of Pulmonary Vein Ectopy

If PV ectopy does not spontaneously develop during EP monitoring or is not sufficiently sustained, one or a combination of several provocative

maneuvers can be tried to induce the arrhythmia, including physiological procedures (e.g., Valsalva maneuvers, carotid sinus massage, or deep breathing), pharmacological agents (isoproterenol, IV infusion at 1 to 8 µg/min; and adenosine, rapid IV injection, 12 mg and then 18 mg, up to 20 to 60 mg), and slow-rate atrial pacing (bursts of 3 to 10 stimuli at 100 to 200 beats/min looking for post-pause ectopy). In addition, in patients who present with AF at the time of ablation, electrical cardioversion of AF often reproducibly induces PACs from the same location as spontaneous PACs, and those PACs that follow cardioversion can potentially reinitiate AF. If AF is not present at baseline, rapid burst atrial pacing to induce AF, followed by electrical cardioversion, can be attempted to identify early postcardioversion PV triggers.

Mapping Pulmonary Vein Ectopy

Electrocardiogram Localization of Pulmonary Vein Ectopy

ATs arising from the PVs are characterized by entirely positive P waves in lead V₁ (in 100% of cases) and across the precordial leads, isoelectric or negative waves in lead aVL in 86%, and negative waves in lead aVR in 96%. Lead aVL can be biphasic or positive in right-sided PV ATs (Fig. 15.21; see eFig. 11.4).¹⁵⁷

Left PV ATs have several characteristics (as compared with right PV ATs), including positive notching in the P waves in two or more surface leads, an isoelectric or negative P wave in lead I, more positive P waves in lead III than in lead II (P wave amplitude in lead III/II ratio greater than 0.8), and broad P waves in lead V₁. Right-sided PV foci usually have positive P waves in lead I (see Fig. 15.21).

ATs arising from the superior PVs invariably have a positive P wave in the inferior leads. In contrast, ATs arising from the inferior PVs can have inverted, low-amplitude positive or isoelectric inferior P waves. However, because of the close proximity of the superior and inferior veins and marked anatomic variation, P wave morphology generally is of greater accuracy in distinguishing right-sided from left-sided PVs, in contrast to distinguishing superior from inferior PVs.¹⁵⁷

ATs arising from the right superior PV are associated with P waves that are narrow and positive in the inferior leads, of equal amplitude in leads II and III, positive in lead V₁, and isoelectric or positive in lead I. The right superior PV is a common site of origin for LA ATs. It is only a few centimeters from the sinus node; hence, activation rapidly crosses the septum via Bachmann's bundle to activate the RA in a fashion similar to NSR, a feature explaining the similarities in P wave morphology. However, whereas the P wave is biphasic in lead V₁ during NSR, it is positive in that lead during right superior PV AT (see Fig. 15.21; see Fig. 11.13).¹⁵⁷

Endocardial Activation Mapping

Initially, the PV of interest is identified based on earliest activation of triggers in the CS and RA catheters. If no sharp bipolar activity is recorded in the RA at least 10 milliseconds before the onset of the ectopic P wave, the ectopic beats are considered to have originated in the LA. Following initial identification, the ablation catheter is placed and maneuvered to the appropriate PV.

Activation mapping within the PV is performed during ectopy. It is important to have adequate frequency of PACs from each focus, to be able to acquire enough points and identify the earliest activation sequence. Electroanatomic mapping or multielectrode mapping catheters, such as the circular catheter (a 10- or 20-pole catheter with a distal ring configuration) or PentaRay catheter (Biosense Webster) or multielectrode arrays (see Fig. 4.3) positioned in the PV, can be of value in mapping the source of ectopy. The ectopic focus is localized inside the selected PV according to the earliest atrial activity relative to the reference electrogram or the onset of the ectopic P wave. PV depolarization during ectopy is marked by a spike (an electrogram of sharp

eFig. 15.9 Mapping of Pulmonary Vein (PV) Ectopy Using a Basket Catheter. The basket catheter is positioned in the left superior PV. Bipolar recordings are obtained from the eight electrodes (1-2, 3-4, 5-6, 7-8) on each of the eight splines (BA through BH) of the basket catheter. *Left*, During normal sinus rhythm (NSR), PV activation propagates from proximal (ostial) to distal, as reflected by earlier activation timing on the proximal basket electrodes than the distal ones (*blue arrows*). *Right*, In contrast, during a premature atrial complex (PAC) originating from this PV, activation occurs earliest deep in the vein and progressively later toward the ostium and the left atrial (LA) exit, resulting in distal to proximal venous activation on the basket catheter recordings (*red arrows*). Note that the PV potentials precede the onset of the P wave on the surface electrocardiogram during PV ectopy, but they occur late after P wave onset during NSR.

Fig. 15.18 Atrial Fibrillation (AF) Initiation From the Right Superior Pulmonary Vein (RSPV). (A) A burst of nonsustained PV tachycardia followed by a second sustained episode. Note that the local cycle length (CL) in the ring catheter recordings from the RSPV is significantly shorter than atrial CL recorded in the coronary sinus (CS) during AF, indicating that this PV is most probably the source and driver of AF. (B) Recordings from the left superior PV (LSPV) in the same patient during spontaneous initiation of AF showing LSPV activity with a CL similar to the atrial CL, a finding suggesting that this PV is activated passively. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus.

Fig. 15.19 Mapping Pulmonary Vein (PV) Ectopy Using a Ring Catheter. The ring catheter is positioned at the ostium of the left inferior PV (LIPV). *Left*, During pacing from the distal coronary sinus (CS) (at left), PV potentials (red arrows) follow the left atrium (LA) potentials. During normal sinus rhythm (middle complex), LA and PV potentials overlap, and they occur in the second half of the P wave. *Right*, During a premature atrial complex (PAC) originating from the LIPV, reversal of the electrogram sequence in the ring catheter recording is observed, with the PV potentials (red arrows) preceding the LA potentials and occurring well before the onset of the P wave on the surface electrocardiogram (dashed line). CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus.

Fig. 15.20 Concealed and Manifest Premature Pulmonary Vein (PV) Complexes. During pacing (S) from the proximal coronary sinus (CS_{prox}), a sharp potential (green arrow) is seen in several PV recording electrodes, followed by a second spike (red arrow) after the QRS complex. This is not a ventricular electrogram, since after the second paced complex, the delayed spike results in a propagated atrial premature complex (blue arrow). After the third stimulus, the main atrial electrogram is seen (green arrow) but the delayed PV spike is absent (open red arrow) due to its being refractory from the prior complex. The last paced complex is similar to the first. CS_{dist}, Distal coronary sinus; CS_{mid}, middle coronary sinus; RIPV, right inferior PV.

Fig. 15.21 Surface Electrocardiogram of Spontaneous Premature Atrial Complexes Originating From the Pulmonary Veins. *LIPV*, left inferior pulmonary vein; *LSPV*, left superior pulmonary vein; *RIPV*, right inferior pulmonary vein; *RSPV*, right superior pulmonary vein.

onset and short duration) preceding the onset of the ectopic P wave by 106 ± 24 milliseconds (range, 40 to 160 milliseconds) (see [eFig. 15.9](#); see [Fig. 15.19](#)). The spike is typically localized, and its amplitude rapidly decreases when the catheter tip is turned or moved a few millimeters. Bystander or far-field activity from contiguous branches can be distinguished by temporal delay or lower amplitude. The spike occurs earliest deep in the vein and progressively later toward the ostium and LA exit, thus resulting in distal-to-proximal venous activation during multipolar recordings (see [eFig. 15.9](#)). A second electrogram component with a slow deflection (depolarization rate [dV/dt] of less than 0.5 mV/ms), reflecting later LA activation, is temporally distinct from the spike inside the vein and then approaches and becomes continuous with the spike at the ostium.

Mechanically induced beats can be prevented by avoiding manipulation of the catheters during the recordings. These beats are excluded

by comparing the ECG pattern and intracardiac activation sequence with the confirmed spontaneous ectopic beats.

If the frequency of spontaneous or induced ectopy remains insufficient, focal mapping and ablation of AF can become difficult. In these cases, the use of a multielectrode basket catheter mapping (see [eFig. 15.9](#)) or noncontact mapping (EnSite) system can map a single beat and help identify the origin of spontaneously occurring PACs and PACs induced following cardioversion of spontaneous or induced AF.

Following successful ablation of the initially targeted PV triggers, a second PV is usually targeted if there are either significant spontaneous isolated PACs (at least 5 per minute), at least two separate PACs inducing AF, or PACs originating from the same PV inducing AF following cardioversion on at least two occasions.

Target of Ablation

The site showing the earliest atrial activity relative to the reference electrogram or onset of the ectopic P wave is targeted by ablation. If more than one PV is arrhythmogenic, the PV producing the most repetitive ectopy or AF-triggering ectopy is targeted first. If ablation of the ectopic focus fails, or the source is more than 1 cm within the PV, electrical isolation of the arrhythmogenic PV should be considered (see later). In addition, ablation can be performed at sites with catheter-induced repetitive ectopy, manifesting as a burst of rapid PACs starting on touching the wall, sustained irritability while at the site, and acute termination of rapid activity on release of the catheter.

Ablation Technique

RF energy is delivered using a 4-mm-tip catheter with a target temperature of 45°C to 50°C and a maximal power output of 25 to 30 W. When an irrigated-tip ablation catheter is used, RF power output is further reduced to minimize the risk of PV stenosis. At successful ablation sites, a rapid burst of PACs originating from that site often develops during RF energy delivery, or an abrupt disappearance of triggering PACs is observed. Cryoablation has also been used to target these sites although the precision of mapping is less (6-mm catheter tip).

Endpoints of Ablation

The endpoint of ablation is elimination of ectopy, spontaneous or induced by provocative maneuvers (using both the same provocative maneuvers and defibrillation protocols as before the ablation). Elimination or dissociation of PV potentials from atrial activity is also a satisfactory endpoint.

Outcome

Early experience with the focal ablation of PV arrhythmias has indicated that the recurrence rate is high and the success rate is only modest, even in experienced laboratories. The suboptimal results can be attributed to the limitations of the technique. Many patients have multiple foci in the same PV or in multiple PVs. Multiple arrhythmogenic PVs are usually associated with older age, longer AF duration, and larger atrial dimensions. In addition, there may be a paucity of spontaneous or inducible arrhythmias during the procedure. The spontaneous occurrence of ectopic beats and paroxysms of AF is unpredictable, and provocative procedures are not consistently effective. Mapping can also be made difficult by frequent recurrences of persistent AF requiring multiple cardioversions. Furthermore, after a successful procedure, new foci may emerge. Remapping usually shows new foci in the ablated vein or in other veins, rather than recurrence of the original focus.

It is also important to recognize that RF ablation inside the PVs carries a significant risk of PV stenosis, which limits the amount of RF energy that can be safely delivered within a PV. Some degree of PV stenosis was detected by increased PV flow velocity on TEE in 42% of

cases in one report. An increased risk of PV stenosis has been associated with the use of RF power more than 45 W.

Focal ablation has been successful only in highly selected patients with frequently recurring paroxysmal AF. Reported rates of a positive outcome using a focal ablation approach to eliminate AF triggers have varied from 38% to 80%. AF recurrences appear to be related to recovery of initially targeted foci or emergence of new nontargeted ones in the same or in a different PV. Because of these safety and efficacy limitations, this method is generally not used currently.

SEGMENTAL OSTIAL PULMONARY VEIN ISOLATION

Rationale

Electrical Isolation of Pulmonary Veins

On the basis of the knowledge of the AF initiation mechanism by focal discharges in the PVs, electrical disconnection at the PV ostium seemed to be a better ablative technique than focal ablation to inactivate focal triggers of AF. Ablation guided by mapping focal ectopy has a high recurrence rate and low long-term success and is limited by unpredictability, inconsistent inducibility, and the risk of inducing AF requiring cardioversion multiple times during the procedure. Moreover, the appearance of multiple sources of AF triggers and the high recurrence rate argue for more extensive ablation strategy. PV isolation has been introduced to address these issues.

PV potentials identify muscular sleeves that extend from the LA into the PVs. These muscular bands are responsible for transmitting triggering impulses from the vein to the LA. The myocardial fibers that envelop the PVs may not be present along the entire circumference of the PV ostia. Therefore to eliminate conduction in and out of a PV, ablation along the entire circumference of the ostium may not be necessary. Instead, ablation can be targeted to the segments of the ostium at which muscle fibers are present, which typically involves RF application to 30% to 80% of the circumference of the PVs. These sites are identified by the presence of high-frequency depolarizations, which represent PV muscle potentials.

The major advantages of this technique are that it eliminates the need for detailed mapping of all PV foci and that there is a clear-cut endpoint of ablation, even when spontaneous arrhythmias are absent, and PV stenosis is far less likely to occur (although it is still possible).

Which Pulmonary Veins to Isolate

Only arrhythmogenic PVs. Focal ablation deep in a PV carries a risk of PV stenosis. Restricting RF delivery to the ostium of the arrhythmogenic PV, as in segmental ostial PV isolation, can help reduce this risk. Furthermore, a more limited ablation approach (as compared with isolation of all PVs) requires shorter procedure and fluoroscopy times and can potentially be safer.

All four PVs. Electrical isolation of only the arrhythmogenic PV was shown to have a limited success rate. Furthermore, identification of the arrhythmogenic PV can be difficult and time consuming, because focal activity can be difficult to observe or induce during the ablation procedure. In addition, the prevalence of multiple arrhythmogenic PVs is high (greater than 70%). Therefore isolation of only the “culprit” PV identified during the procedure may allow the emergence of focal ectopy from other PVs, which can potentially cause AF recurrence after the procedure. Moreover, electrical disconnection may not be achieved by ostial ablation to only the targeted PV in patients with electrical connections between the PVs (i.e., across the carina between left PVs).

Evidence has suggested that almost all PVs are capable of generating the premature depolarizations that trigger AF, and the upper PVs are

responsible for most AF triggers (the left superior PV is the vein with the longest muscular sleeve). Only a few (0% to 30%) foci have been identified in the inferior PVs (the right inferior PV is the least important source of triggers). Therefore unless no PV potentials are present at its ostium (a rare finding), all four PVs should be targeted, whenever feasible.

Circumferential Mapping of Pulmonary Vein Potentials

Ring Catheter Mapping

A deflectable decapolar catheter with a distal ring configuration is advanced sequentially into each PV and is used for ostial mapping (eFig. 15.10). The ring catheter enables circumferential mapping of the PV ostia perpendicular to the axis of the vein. Lasso catheters are of different sizes. The selection of a 15-, 20-, or 25-mm-diameter Lasso catheter can be guided by the estimated size of the PVs on preprocedural imaging (CT or CRM). PV angiographically also can be performed, but is rarely needed (see eFig. 15.8). Because of the highly variable sizes of PV ostia, fixed-diameter catheters may not always achieve catheter stability and optimal electrogram recordings. In some cases, suboptimal positioning, poor wall contact, and poor stability of an inappropriately sized circumferential catheter underestimate the number of PV potentials and can result in failure to isolate the PV completely because of undetected residual PV-atrial electrical connections. Some of those issues can be addressed by using an expandable 15- to 25-mm-diameter ring catheter. The expandable ring catheter is introduced into each PV and withdrawn to the most proximal stable position, with optimal wall contact ensured by progressive loop expansion. These catheters enable more proximal and stable placement and optimal wall contact at the PV ostia. This is important because the ablation target is not within the ostia, but in the atrial tissue proximal to the LA-PV junction.

The ring catheter is positioned within a PV and gradually withdrawn to within 5 mm of the ostium. It is important to position the ring catheter at the ostium of the PV; when it is positioned too deeply in the PV, PV potentials can be missed (Fig. 15.22). Subsequently, circumferential mapping of the PV is performed by obtaining 10 bipolar electrograms (1-2, 2-3, up to 10-1 electrode pairs) with the circular arranged electrodes of the ring catheter. The band-pass settings for the bipolar recordings are 30 to 500 Hz. Pacing from each pair of electrodes from the ring catheter has been used by some to ensure appropriate ring catheter sizing (80% of electrode pairs resulting in capture) and to demonstrate conduction from the veins to the atrium before ablation. Alternatively, the ablation catheter may be used to pace locations in the PV that capture and conduct to the atrium; these sites are tagged on the electroanatomic mapping system for subsequent use after PV isolation; pacing at these sites without conduction to atrium signifies PV exit block (see below).

Ring catheters with 20 poles are also available and can offer higher resolution circumferential mapping and improve the differentiation of PV from LA potentials. The conventional wide bipolar electrograms record the PV potentials, as well as the larger LA potentials, which can obscure or mimic the PV potentials. In contrast, the high-resolution electrograms minimize the extent of far-field electrogram detection and display very small or completely absent LA potentials. In the context of PV isolation during sustained AF, improved discrimination between atrial and PV potentials can facilitate the recognition of complete PV disconnection and possibly limit the number of unnecessary RF applications. On the other hand, when a ring catheter and closely spaced electrodes make poor contact with the PV wall or are placed deep within the PV, near-field potentials may not be seen, which leads to under-detection of PV potentials.

The use of a navigational system (CARTO-3, EnSite NavX, or Rhythmia) in ostial segmental PV isolation provides accurate nonfluoroscopic

eFig. 15.10 Fluoroscopy Views (Right Anterior Oblique [RAO] and Left Anterior Oblique [LAO]) of the Ring Catheter Positioned at the Ostium of the Four Pulmonary Veins (PVs). Panels from left to right: Left superior PV (LSPV), left inferior PV (LIPV), right superior PV (RSPV), and right inferior PV (RIPV). Note that during ablation, the ablation catheter (ABL) is always positioned at the atrial side of the ring catheter. CS, Coronary sinus.

Fig. 15.22 Recordings From a Ring Catheter in the Right Superior Pulmonary Vein (RSPV). (A) The ring catheter is situated too deep in the vein; recordings suggest no pulmonary vein (PV) potentials. (B) The ring catheter pulled back 1.5 cm, showing abundant PV potentials. *Abl_{dist}*, Distal ablation site; *Abl_{prox}*, proximal ablation site; *CS_{dist}*, distal coronary sinus; *CS_{mid}*, middle coronary sinus; *CS_{prox}*, proximal coronary sinus; *His_{prox}*, proximal His bundle.

visualization of multiple catheter tips and curves (including the ring catheter) and allows a real-time assessment of wall contact and catheter stability, as well as assessment of the spatial relationship between ablation and ring catheters. Furthermore, these systems can take a shadow or snapshot of the position of the ring catheter and, hence, facilitate accurate repositioning of the catheter in the case of displacement from its original location. Also, the system enables labeling the electrodes on the ring catheters, thus allowing precise navigation of the ablation catheter to the labeled pole of the ring catheter without the assistance of fluoroscopy.

Mapping During Normal Sinus Rhythm

It is preferable to perform PV mapping during NSR or atrial pacing whenever possible because AF reduces PV potential amplitude and makes them more difficult to identify. Therefore if the patient is in AF, electrical cardioversion is usually performed to restore NSR. Ibutilide or amiodarone can also be administered intravenously to prevent immediate recurrences of AF after cardioversion. Isolation can still be achieved if AF persists, however (see below).

PV mapping during NSR typically shows double or multiple potentials that are usually recorded in a progressively later temporal sequence, synchronous with the first (right PVs) or second (left PVs) half of the

sinus P wave (Fig. 15.23). The first low-frequency potential reflects activation of the adjacent LA. The latest high-frequency electrograms indicate PV potentials.

Identification of PV potentials using pacing maneuvers. PV potentials often are fused with the far-field LA electrograms but can be identified by their high-frequency appearance. Not uncommonly, an isoelectric interval separates the far-field LA electrogram and the near-field PV potential. The basis for this separation is unclear; however, evidence has suggested that there is an area of slow conduction at the proximal PV. The interval between the far-field electrogram and the PV potential can differ based on the site of pacing, likely related to fiber orientation (anisotropy), which can make it easier to enter the vein from certain wavefront directions or because the far-field electrogram is not actually coming from the LA but is arising from a neighboring structure. Therefore pacing from different atrial sites (most commonly high RA or distal CS) can help separate PV potentials from far-field atrial signals (see Figs. 15.23 and 15.24). Furthermore, incremental rate atrial pacing and premature atrial stimulation from the same atrial site can sometimes result in conduction delay between the LA and PV at the PV ostium, which often exhibits decremental conduction properties (Fig. 15.25). Thus if a complex electrogram is seen on a PV mapping catheter and, with faster or premature pacing, one of

Fig. 15.23 Differential Atrial Pacing to Identify Pulmonary Vein (PV) Potentials. *Left panel*, During normal sinus rhythm (NSR), the atrial and left superior PV (LSPV) potentials are superimposed and distinction of PV potentials from left atrial (LA) electrograms is difficult, if not impossible. *Middle panel*, During coronary sinus (CS) pacing, PV potentials (shaded area) are delayed relative to LA potentials and are thus readily discerned. *Right panel*, Pacing from within the LSPV also shows a clear delineation of PV versus LA potentials; in this case, PV potentials precede LA potentials. *Abl_{dist}*, Distal ablation site; *Abl_{prox}*, proximal ablation site; *CS_{dist}*, distal coronary sinus; *CS_{mid}*, middle coronary sinus; *CS_{prox}*, proximal coronary sinus; *His_{prox}*, proximal His bundle.

the potentials is seen to occur later after the far-field atrial electrogram, the delayed signal likely is a PV potential.

Right-sided PVs are typically mapped during NSR or RA pacing. For left PVs, the ostial PV potentials are sometimes not obvious during NSR because of the superimposed LA potential; therefore pacing from the distal CS (at a pacing cycle length [PCL] of 600 milliseconds) allows their separation and easy recognition of PV potentials (see Fig. 15.23). However, even during CS pacing, the atrial and PV potentials still can overlap in approximately 50% to 60% of left PVs (see Fig. 15.25). The separation can be less evident in the posterior PV antrum, which is closer to the CS. Pacing from the LAA can help in this situation.

Because of the anatomic proximity of the PVs to several other structures that are electrically active, complex signals can be recorded by a catheter placed in the PV. For example, a catheter placed in the left superior PV can potentially record electrical activity in the LA, LAA, left inferior PV, and ligament of Marshall. Similarly, a mapping catheter placed in the right superior PV may record electrical activity in the right middle PV, right inferior PV (particularly a superior branch), RA, LA, and SVC (Fig. 15.26). When a typical PV potential is recorded in a left PV, the far-field electrogram usually is coming from the LA. When mapping catheters are placed in the right-sided PV, often the main far-field electrogram is the RA electrogram, and the second far-field electrogram, if seen, is the LA electrogram. In general, only the PV potential itself is near-field; all other structures picked up by the antenna

of the mapping catheter are blunted and far-field. However, this criterion alone is insufficient for identifying the true PV potential. For example, if a catheter is deep within the left superior PV, where no PV musculature is present, the LAA electrograms will appear relatively near-field. Similarly, when RF ablation has already been performed, edema near the PV ostium and inadvertent ablation within the PV (more frequent than generally realized) will cause PV potentials to be less sharp and less near-field in character. Various pacing maneuvers can differentiate from among these possibilities and can help exclude or prove a relationship of various components of the electrogram recorded from a PV to anatomic structures surrounding that particular PV. An important feature of far-field potentials is that they should be seen only on electrodes that “face” the structure in question; for instance, with a catheter in the left superior PV, signals that are recorded on electrodes adjacent to the LAA can represent far-field recordings from that structure, whereas signals visible only on electrodes at the posterior aspect of the left superior PV cannot be far-field LAA potentials (Fig. 15.27).

One pacing maneuver commonly used when complex electrograms are recorded on a mapping catheter placed in a PV is pacing at specific sites likely to be responsible for the components of the electrogram. The premise of such a maneuver is that pacing from a particular site causes the electrogram originating from that site to occur earlier, close to the pacing stimulus. For example, because of the proximity of the LAA to the left PVs (especially the left superior PV), far-field LAA

Fig. 15.24 Depiction of Differential Activation of Left Atrial (LA) and Pulmonary Vein (PV) Potentials. The LA is opened from the front, showing orifices of PVs; a ring catheter is in the left superior PV (LSPV). Red strands indicate a muscular PV fascicle extending into the LSPV; green arrows indicate propagation into the PV over the fascicle. (A) During sinus rhythm, the wavefront propagates as indicated by blue curved lines and activates LA tissue around the PV and the PV fascicle at almost the same time, yielding a summated electrogram at right. (B) During pacing from the coronary sinus (CS, at asterisk), the wavefront approaches from a different direction and activates LA muscle well before the PV fascicle is entered, accounting for the delay in PV potential inscription at right. CS_{dist}, Distal coronary sinus; CS_{mid}, middle coronary sinus; CS_{prox}, proximal coronary sinus; LIPV, left inferior pulmonary vein; RIPV, right inferior pulmonary vein; RSPV, right superior pulmonary vein.

potentials can be recorded in these PVs, and PV potentials can be confused with LAA potentials. These potentials are distinguished from PV potentials by differential pacing from the distal CS and LAA. If a pacing catheter is placed in the LAA and LAA capture is documented, the LAA component of the complex electrogram will occur early and will be drawn toward the pacing artifact (Fig. 15.28). Thus the electrogram that moves the closest to the pacing stimulus can be diagnosed as originating from the LAA. Similar reasoning can be applied when pacing in an ipsilateral PV—if a component of the electrogram recorded in the left superior PV is, in fact, a left inferior PV potential.

LA electrograms, particularly when fragmented secondary to partial ablation, can also be mistaken for a PV potential, and pacing from a site in the LA close to, but not within, the PV (perivenous pacing) can help define the LA electrogram component of a complex PV recording. When pacing from a perivenous location, the LA signal will occur very close to, and often will merge with, the saturation artifact related to

the pacing spike. However, because pacing is being performed proximal to the site of ostial delay, the PV potential remains unchanged or may occur with slightly more delay. The shift of the LA signal, which now is being captured by perivenous pacing, toward the pacing spike indicates the origin of that component of a complex signal. Differentiation of RA, LA, and PV potentials recorded within right-sided PVs can also be achieved using similar maneuvers (Fig. 15.29).

Multisite simultaneous pacing is an extension of the basic concept that pacing from a particular site will cause earlier occurrence of the electrogram arising from that site. For example, pacing from the CS alone is compared with simultaneous pacing from both the CS and LAA, with specific attention paid to the transition in the recorded electrogram between single-site (e.g., CS only) and dual-site (e.g., CS and LAA) pacing, which can help immediate distinction of the various components of a complex signal recorded within the PV.

Ablation target sites. Target sites for ablation are selected by identifying the earliest bipolar PV potentials or the unipolar electrograms with the most rapid (sharpest) intrinsic deflection on high-speed recordings (150 to 200 mm/s) that have equivalent or earlier activation relative to the earliest PV potential recorded on the adjacent ring catheter recording sites (Fig. 15.30).

Electrogram polarity reversal can also be used as an additional indicator of breakthroughs from the LA to the PVs and identify potential ablation targets. *Polarity reversal* is defined as a sudden change in the main deflection of the PV potential. The reversal occurs as the wavefront of activation propagates radially in the PV from its connection with the LA, thus reaching contiguous bipolar recording electrodes in opposing directions (see Figs. 15.30 and 15.31).

Mapping During Atrial Fibrillation

Although segmental ostial PV isolation is accomplished most efficiently during NSR, maintaining NSR during an ablation procedure may not be readily achievable, particularly in patients with longstanding persistent AF. During an ongoing episode of AF, PV potentials can be obscured during the chaotic electrical activity of AF. Nevertheless, segmental ostial PV isolation was found to be as feasible and successful during AF as during NSR. An advantage of mapping during AF is that it obviates the need for the administration of antiarrhythmic drugs and for multiple electrical cardioversions in patients with frequent AF recurrences during the procedure. Two approaches have been described for PV isolation during AF: the first uses intermittent bursts of PV tachycardia to guide PV isolation, and the second uses organized PV potentials during AF to guide PV isolation.

Intermittent PV tachycardia. Prior studies demonstrated that rapid rhythms arising in the PVs (intermittent PV tachycardia) are common during AF and can play an important role in the maintenance of AF, or they can be a marker of an arrhythmogenic PV that triggers AF. Those intermittent bursts of PV tachycardia indicate the presence of an underlying arrhythmogenic muscle fascicle near the ostial recording sites and therefore can be used to guide segmental ostial ablation to isolate the PVs during AF.

During AF, the PVs are sequentially mapped with the ring catheter to assess the presence of intermittent PV tachycardia, defined as a PV rhythm that intermittently has a CL shorter than the AF CL recorded in the adjacent LA. When intermittent PV tachycardia is recorded on several electrodes, the ostial site corresponding to the most rapid intrinsic deflection of the unipolar electrogram should be targeted by RF applications. If PV tachycardia is not observed, ostial sites that display a high-frequency bipolar PV potential or rapid unipolar intrinsic deflection during AF can alternatively be targeted for ablation.

If AF terminates during ablation, PV potentials are then assessed during NSR and atrial pacing. If there is evidence of residual conduction

Decremental conduction at the PV ostium

Fig. 15.25 Decremental Conduction at the Pulmonary Vein (PV) Ostium. During coronary sinus (CS) drive pacing, complex electrograms (blue arrows) are recorded by the ring catheter positioned at the ostium of the left superior PV (LSPV). An atrial extra-stimulus from the distal CS results in conduction delay between the left atrium (LA) and the PV at the PV ostium. Therefore PV potentials (red arrows) become delayed and separated from atrial electrograms. ABL, Ablation catheter; CS_{dist}, distal coronary sinus; CS_{prox}, proximal coronary sinus.

Right superior PV

SVC

Fig. 15.26 Superior Vena Cava (SVC) Activity Recorded in the Right Superior Pulmonary Vein (PV). *Left panel*, Recordings from a ring catheter positioned at the ostium of the right superior PV showing high-amplitude PV potentials that disappear midway through the recording because of isolation of the vein with radiofrequency ablation. Another set of lower amplitude signals (arrows) remains and was present prior to PV isolation. *Right panel*, These potentials represent far-field SVC recordings, shown as sharp near-field recordings after the ring catheter is positioned in the SVC. Abl_{dist}, Distal ablation site; Abl_{prox}, proximal ablation site; CS_{dist}, distal coronary sinus; CS_{mid}, middle coronary sinus; CS_{prox}, proximal coronary sinus; His_{prox}, proximal His bundle.

Fig. 15.27 Left Pulmonary Veins Versus Left Atrial Appendage (LAA). Cutaway view of the left atrium showing the inside of the lateral aspect. A ring catheter is depicted in the left superior pulmonary vein (LSPV). Far-field recordings can be made from adjacent structures on certain electrodes of the ring catheter as indicated, such as LAA or left inferior pulmonary vein (LIPV).

Fig. 15.28 Differential Pacing for Identification of Pulmonary Vein (PV) Potentials. During electrical isolation of the left superior PV (LSPV) in normal sinus rhythm (NSR), residual electrograms were persistent despite multiple radiofrequency (RF) applications. The initial electrograms (red arrows) were consistent with left atrial (LA) far-field activity. However, the late electrograms (shaded area) were suggestive of PV activity. Pacing from the distal coronary sinus (CS) resulted in anticipation of both early and late electrograms. Pacing via the ablation catheter (ABL) positioned in the LA appendage (LAA) resulted in disappearance of the late electrograms (i.e., those electrograms merged with the saturation artifact related to the pacing spike), a finding suggesting that those electrograms in fact represented LAA activity. Therefore the presence of PV potentials was excluded, and no further RF ablation was necessary. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus.

Fig. 15.29 Differential Pacing to Distinguish Pulmonary Vein (PV) Potentials From Right and Left Atrial Potentials. During electrical isolation of the right superior PV (RSPV) in normal sinus rhythm (NSR), residual electrograms (blue shaded area and red arrows) were persistent despite multiple radiofrequency (RF) applications. Pacing from the right atrial (RA) appendage (RAA) resulted in disappearance of the earlier electrograms (red arrows; i.e., those electrograms merged with the saturation artifact related to the pacing spike), a finding suggesting that those electrograms in fact represented RA activity. During pacing just outside the ostium of the RSPV (using the ablation catheter), the second set of electrograms (shaded area) disappeared, whereas the RA electrograms (red arrows) persisted in the ring catheter recordings, indicating that the second set of electrograms in fact represented left atrial activity. Therefore the presence of PV potentials was excluded, and no further RF ablation was necessary. ABL, Ablation catheter; CS_{dist}, distal coronary sinus; CS_{prox}, proximal coronary sinus; HRA, high right atrium.

Fig. 15.30 Segmental Ostial Pulmonary Vein (PV) Isolation. During circumferential ostial PV mapping using a ring catheter, electrical connections between the left atrium (LA) and the PV (target sites for ablation) are identified by recording the earliest bipolar PV potentials with electrogram polarity reversal on adjacent poles (shaded electrograms). Note that the distal bipoles of the ablation catheter record even an earlier sharp PV potential (arrows). The presence of ablation artifact on the recording from a specific ring catheter pole confirms the pole the catheter is on and that the catheter is in the same plane as the ring catheter. Catheter ablation at that site results in complete elimination of PV potentials and LA-PV block (last complex). ABL, Ablation catheter; CS_{dist}, distal coronary sinus; CS_{prox}, proximal coronary sinus.

Fig. 15.31 Bipolar Electrogram Polarity Reversal. The ring electrode catheter (electrodes numbered) is situated in the ostium of the left superior pulmonary vein (LSPV); a strand of atrial muscle crosses from the left atrium (LA) to the pulmonary vein (PV) (red) and branches within the vein. The arrow indicates propagation of the wavefront of activation from the LA to the PV. The strand crosses at electrode 7; recordings from surrounding bipoles indicate the direction of propagation away from (negative deflection) or toward (positive deflection) the bipole. The point at which the polarity reverses from positive to negative is where the strand crosses into the PV.

over a PV fascicle, RF energy is delivered at these ostial sites during NSR or atrial pacing. On the other hand, if AF is still present after isolation of a PV, electrical cardioversion is performed. If AF recurs, other PVs are isolated during AF and, if NSR is maintained, the remaining PVs are isolated during NSR or atrial pacing.

Organization of PV potentials. PV potentials can be classified at baseline as organized (have a consistent activation sequence for more than 10 seconds) or disorganized (activation sequence on the ring catheter varies from beat to beat). Approximately 37% of PVs have organized PV potentials (more for inferior than superior PVs—53% vs. 26%; Fig. 15.32). When the PV activation pattern is organized (from the beginning or after some anatomically guided RF applications), the area showing the earliest activation or demonstrating polarity reversal on the ring catheter is targeted.

For disorganized PV potentials, ablation is performed circumferentially around the ring catheter on the ostial side of the PV. The top and bottom segments of the PV are targeted first because of the high prevalence of LA-PV breakthroughs at these sites. In most cases, initial RF applications result in organization of PV activity. This activity is probably secondary to progressive reduction of LA-PV breakthroughs that diminishes the mass of fibrillatory conduction within the PV and channels the electrical activity through the last remaining fascicles connecting the LA to the PV, thereby activating the PV in an organized fashion. This consequently enables EP-guided PV isolation.

Organized PV activity can represent fewer LA-PV connections and therefore may require fewer RF applications than PVs with disorganized activity. This may explain the greater frequency of organized activity in the inferior PVs, presumably because of the presence of less extensive muscular sleeves in these veins as demonstrated by pathological studies.

Fig. 15.32 Pulmonary Vein (PV) Isolation During Atrial Fibrillation (AF). Initially (at left), PV potentials are disorganized. During radiofrequency (RF) application at the PV ostium, the PV potentials become organized. See text for discussion. ABL, Ablation catheter; CS_{dist}, distal coronary sinus; CS_{prox}, proximal coronary sinus.

Basket Catheter Mapping

The basket catheter (Constellation, Boston Scientific) is composed of 64 electrodes mounted on 8 flexible, self-expanding splines (see Fig. 4.3). Each spline is identified by a letter (from A to H) and each electrode by a number (distal 1 to proximal 8). The 32 bipolar electrograms provide 3-D mapping of PV activation.

Basket catheter positioning. After transseptal access is gained, an 8.5 Fr soft-tipped guiding sheath with a 90- or 120-degree curve or, preferably, a deflectable sheath, is introduced into the PVs. A steerable ablation catheter can help introduce the sheath into the PVs (especially the inferior PVs). The ablation catheter is introduced through the sheath, and once it is engaged in the PV, the sheath is advanced over the ablation catheter. Once the sheath is in place in the PV, the steerable catheter is removed and is replaced by the basket catheter. The basket catheter is introduced into the sheath so that the tip of the basket catheter reaches the tip of the sheath; the sheath is then pulled back to allow expansion of the basket catheter (eFig. 15.11). Alternatively, the basket catheter is inserted into the PVs with the sheath positioned in the LA. However, although this technique was found to be safe because of the very flexible splines of the basket catheter, extreme caution is required to avoid venous perforation by the stiff catheter tip.

A basket catheter with a diameter of 31 mm is chosen when the diameter of the main PV trunk is 26 mm or smaller, and a basket catheter with a diameter of 38 mm is used when the PV diameter is greater than 26 mm or when there is a common ostium. The PV diameter is determined by preacquired CMR, CT scanning, or PV angiography. The position of the basket catheter in relation to the PV ostium can be determined by PV angiography (Fig. 15.33) or ICE. If necessary, the basket catheter is retracted to obtain optimal contact to the main trunk and ostium of the PV.

Basket catheter mapping. The basket catheter is deployed within the target PV with its most proximal electrodes positioned at the PV ostium, as determined by selective PV angiography. PV activation can be followed during NSR or CS pacing propagating through the four levels of bipolar electrograms from proximal ostial (¼) to distal (½) inside the PV. During ectopic beats or initiation of AF, the activation can be followed from the source of ectopy to its exit to the LA (see eFig. 15.9).

Ablation is performed at the junction between the PV and the LA targeting the site of earliest PV potential recording or shortest atrial-PV potential delay. The location of the ostium is determined by electrogram morphology and by noting the shape of the basket catheter

because it conforms to the PV, and ostial anatomy can be confirmed by angiography.

Advantages of the basket catheter. The basket catheter offers higher resolution as compared to the ring catheter for mapping of the LA-PV junction. In addition, the basket catheter provides information about the anatomy of the PV, such as exact ostium localization, because the basket catheter takes the shape of the PV (see Fig. 15.33) and allows 3-D reconstruction of the PV activation from the ostium to deep inside the PV.

Furthermore, the distal poles of the basket catheter can be used to monitor changes in the activation sequence in real time and to demonstrate the effects of ablation at the ostium as lesions are created. They also provide an immediate indication of successful PV isolation by the disappearance of the distal PV potentials. The system also helps identify areas near the PV ostium with fragmented potentials and with discharging ostial foci, which can be localized in a single beat.

Basket catheter–guided PV isolation can potentially minimize the risk of PV stenosis, first by reducing the number of RF applications and second by avoiding ablation inside the PV, because the basket catheter allows localization of the PV ostium during the entire procedure. Thus the use of complementary navigation systems or ICE appears to be nonessential when using the basket catheter for PV isolation.

Disadvantages of the basket catheter. Carbonizations, which appear as dark material attached to the basket catheter electrodes or splines, can form after ablation on the splines of the basket catheter, which can potentially cause embolism. Carbonizations are thought to be caused by the concentration of RF energy on the thin splines that results in very high local temperatures that induce denaturation of serum proteins. However, the risk of carbonization can be diminished with the use of an irrigated-tip catheter as opposed to conventional ablation catheters.

Another disadvantage is that the basket catheter is nondeflectable and has limited maneuverability, and it requires a special sheath with a limited number of preshaped curves. Sometimes, it can be challenging to introduce a basket catheter into the inferior PVs. The use of a deflectable transseptal sheath can facilitate catheterization of the PVs.

In addition, the splines may contact one another when the basket catheter is positioned within a relatively small PV, thereby inducing electrical artifact (see Fig. 15.33). Similarly, the splines may not always be equally spaced relative to the circumference of the PV. As a result, areas in which several splines are clustered may be densely mapped, whereas other regions are less densely recorded.

Fig. 15.33 Pulmonary Vein (PV) Angiography to Define Basket Catheter Positioning. Fluoroscopic right anterior oblique and left anterior oblique views of angiography of the right superior PV (RSPV) with a basket catheter positioned in the vein. Note that the basket catheter takes the shape of the PV and provides anatomic information about the location of the ostium and size of the PV. CS, Coronary sinus.

eFig. 15.11 Left Anterior Oblique (LAO) Fluoroscopic Views of Basket Catheter Positioned in the Four Pulmonary Veins (PVs). Target of Ablation

The objective of the mapping and ablation procedure is to identify PV potentials along the circumference of the PV ostium and ablate to completely eliminate these potentials. Electrical isolation of all PVs is performed without attempting to identify the PVs demonstrating arrhythmogenicity. RF ablation is targeted to the ostial portion of the breakthrough segments (electrical connections) connecting the LA to the PV, which are identified as the earliest PV potentials recorded from the ring catheter. The PV potential reflects the activation of muscular LA bands extending into the PV with longitudinal, oblique, or complex courses and ending in a cul-de-sac or even looping back in the LA. The source, its course within the PV, and its exit into the LA may all be considered appropriate individual targets for ablation. The PV potential is recorded over a broader area proximally, but with great variability. Therefore a few seconds of energy application can be sufficient at some proximal sites to eliminate downstream PV muscle activity, whereas wide or repeated RF applications may have been required in others.

Once the presence of the PV potentials along the PV circumference is defined on the ring catheter, target sites for ablation are selected by identifying the earliest bipolar PV potentials or the unipolar electrograms with the most rapid (sharpest) intrinsic deflection on high-speed recordings (150 to 200 mm/s) that had equivalent or earlier activation relative to the earliest PV potential recorded on the adjacent ring catheter recording sites (see Fig. 15.30). The ablation catheter then is maneuvered to a position adjacent to the target electrode pair of the ring catheter and withdrawn to the edge of the ostium (at the atrial side of the ring catheter). RF ablation is performed within 5 to 15 mm of the PV ostium; the exact location usually depends on catheter stability. This is safer (regarding the risk of PV stenosis) than more distal applications, especially in smaller veins.

Several PV potential electrogram characteristics predict a successful ablation site: (1) timing of the (unipolar and bipolar) PV potential electrogram recorded by the ablation catheter equal to or earlier than the earliest PV potential recorded by the ring catheter (see Fig. 15.30); (2) larger (unipolar and bipolar) electrogram amplitude; (3) steeper intrinsic deflection of the unipolar electrogram; and (4) identical morphologies of the unipolar electrograms recorded by the ablation catheter and by the contiguous electrode of the ring catheter.

Ablation Technique

A temperature-controlled, 4- or 8-mm-tip deflectable catheter or an irrigated-tip ablation catheter can be used. For 8-mm-tip catheters, RF ablation is performed with the maximum temperature set at 45°C to 55°C, the power set at 70 W or lower, and for a duration of 20 to 60 seconds. Power limit is usually reduced to 25 W for the case of a left inferior PV and to 20 W if the PV diameter is less than 15 mm. For irrigated-tip catheters, power is set at 25 to 35 W or lower and temperature at 40°C or lower. RF applications are delivered for a maximum of 60 seconds to achieve an impedance drop of 5 to 10 Ω at the ablation site. RF application can be repeated or prolonged when a change occurs in activation or morphology of the PV potentials, as determined by circumferential mapping recorded downstream. The presence of high-amplitude electrical artifact on the recording from a specific ring catheter pole confirms the pole with which the ablation catheter is in contact and that the catheter is in the same plane as the ring catheter (see Fig. 15.30); ablation should not be performed at such locations, since (1) if the ring catheter is inside the PV, so is the ablation catheter tip, and (2) carbonization may occur on the ring catheter electrode in contact with the ablation electrode.

A successful ablation site is defined as a site at which an application of RF energy results in elimination of a PV potential at more than one

ring catheter recording sites or delay (shift) of a PV potential by at least 10 milliseconds at more than two ring catheter recording sites (Fig. 15.34). Once a shift or elimination of PV potentials at some ring catheter poles is achieved, the ablation catheter is adjusted to target the new ring catheter pole recording the now earliest PV potential. This maneuver is repeated until the whole PV is electrically isolated. Complete electrical isolation of the PV is defined as complete entrance block into the PV during AF and elimination or dissociation of all ostial PV potentials during NSR and atrial pacing (see Fig. 15.34), as well as exit block from the vein (see later).

The extent of the circumference ablated is variable among PVs. When ablation is performed proximal to the PV ostium or during AF, more circumferential ablation is often required to achieve PV isolation. Occasionally, electrical connections exist between ipsilateral PVs, and elimination of these connections is important only when isolation of only one of the two PVs is the goal of the ablation procedure. The electrical connections between PVs are identified by mapping the earliest activation at the ostium of an untargeted PV during pacing inside the targeted PV; then, ablation is performed at this untargeted PV ostium to achieve electrical disconnection.

When the basket catheter is used for PV mapping, it is recommended to use an irrigated-tip catheter at a maximum temperature of 45°C, maximum power of 25 to 30 W, and flow rate during ablation of 17 mL/min.

Endpoints of Ablation

Electrical Disconnection of the Pulmonary Vein

Complete PV electrical disconnection is confirmed by the demonstration of bidirectional block at the LA-PV junction, that is, the absence of conduction from the LA to PV (entry block) and in the opposite direction from PV to LA (exit block).

In general, the presence of entrance block appears to be effective in predicting bidirectional block across the PV-LA junction, and is commonly used as the primary endpoint in AF ablation. However, permanent PV exit conduction block is the ultimate goal of PV electrical isolation for prevention of PV-induced AF and, hence, demonstration of the presence of exit block is a reasonable endpoint for PV isolation.

Entrance block. Entrance block into the PV (i.e., LA-PV conduction block) can be recognized by the complete elimination of all ostial PV potentials recorded by the ring catheter (during NSR, atrial pacing, or AF) or the appearance of dissociated PV potentials (see Figs. 15.34 and 15.35).

Exit block. Exit block is verified by the absence of conduction from the PV to the LA during intra-PV pacing or during spontaneous PV ectopy or PV tachycardia (eFig. 15.12). The observation of spontaneous dissociated potentials from the PVs following their isolation confirms exit block. The presence of exit block also can be verified by PV pacing performed from multiple sites in a circumferential manner as possible by using the bipoles of the ring catheter or mapping-ablation catheter positioned distal to the PV and LA junction. When local PV capture is difficult to demonstrate because of the pacing stimulus masking the PV electrogram, decremental pacing can be used to unmask local PV potentials.

Prior reports suggested that demonstration of entry block into the PV is not a sufficient condition to conclude exit block. In one report, residual PV-LA exit conduction after achieving entrance block (i.e., unidirectional LA-PV block) was demonstrated by pacing maneuvers in more than 40% of the PVs, suggesting that the demonstration of only entrance block is an insufficient endpoint (eFig. 15.13). The fact that tachycardias can be induced in isolated PV segments emphasize the importance of achieving PV exit block. However, more recent reports found that the true incidence of unidirectional block had been overestimated (the

Electrical isolation of the left superior PV

eFig. 15.12 Electrical Isolation of the Left Superior Pulmonary Vein (LSPV). Complete electrical isolation of the LSPV resulted in termination of atrial fibrillation (AF) and conversion to normal sinus rhythm on the surface electrocardiogram and coronary sinus (CS) recordings, whereas AF continued in the LSPV (PV-left atrial exit block). ABL, Ablation catheter; CS_{dist}, distal coronary sinus; CS_{mid}, middle coronary sinus; CS_{prox}, proximal coronary sinus.

eFig. 15.13 Pulmonary Vein (PV)–Left Atrium (LA) 2:1 Exit Block. The ring catheter is positioned at the ostium of the left superior PV. During pacing using the ablation catheter positioned more distally in the vein, consistent capture of PV potentials is shown (*blue arrows*) but only every other PV potential conducts to LA (*red arrows*). Note very long delay between the stimulus and the P wave of the conducted complex (*black arrow*). *Abl_{dist}*, Distal ablation site; *Abl_{prox}*, proximal ablation site; *CS_{dist}*, distal coronary sinus; *CS_{mid}*, middle coronary sinus; *CS_{prox}*, proximal coronary sinus; *His_{prox}*, proximal His bundle.

Fig. 15.34 Electrical Isolation of the Right Superior Pulmonary Vein (PV). *Left panel*, Baseline recordings from a ring catheter situated at the PV ostium. During coronary sinus (CS) pacing, left atrial (LA) and PV potentials overlap. *Middle panel*, After some encircling ablation, some of the PV potentials are shifted to a later time (arrow) and become separated from far-field LA electrograms. *Right panel*, On completion of isolation, no PV potentials are visible (entrance block into the PV). *Abl_{dist}*, Distal ablation site; *Abl_{prox}*, proximal ablation site; *His_{prox}*, proximal His bundle; *CS_{dist}*, distal coronary sinus; *CS_{mid}*, middle coronary sinus; *CS_{prox}*, proximal coronary sinus.

incidence in the latter studies was 1.5% to 16%), and that exit pacing maneuvers can erroneously indicate PV-LA exit conduction due to capture of far-field structures neighboring the PV ostium or due to the presence of electrical connections between ipsilateral PVs. Therefore it is critical to recognize these phenomena during intra-PV pacing to avoid unnecessary ablation.

LAA capture during pacing from the left superior PV, and SVC capture during pacing from the right superior PV can masquerade as persistent conduction from the PV to the LA. True exit conduction is considered to be present if PV-LA conduction occurs during pacing from the posterior aspect of those veins (i.e., away from the anteriorly positioned LAA and SVC). Two additional maneuvers can be employed to distinguish the presence or absence of exit block. If LA capture is observed with pacing from the anterior aspect of the PV, the pacing output is gradually decreased to lose capture of the far-field structure while maintaining PV capture. The observation of local PV capture with exit block during this maneuver is consistent with a diagnosis of pseudo-exit conduction during high output pacing caused by far-field capture. In addition, the presence of early activation within the far-field structure (recorded by a catheter positioned in the LAA or SVC), closely coupled to the pacing stimulus and preceding local PV activation during pacing from the anterior aspect of the PV, is also diagnostic of pseudo-exit conduction.

Intra-PV pacing maneuvers can unmask electrical connections between ipsilateral PVs (present in up to 18% of patients), which

manifest as intact LA conduction during intra-PV pacing after elimination of all potentials in that PV, thus indicating unidirectional block. This is relevant when only one (and not all) PV is targeted for isolation. Exit block can be inferred if sites of PV capture (during NSR) were located on the electroanatomic mapping system prior to isolation, and pacing at such sites after isolation show no propagation to the LA.¹⁵⁸

Waiting Period and Pharmacological Provocation

Early recovery of PV conduction can be observed in up to 93% of patients and 50% of PVs, with about one-third of the PVs demonstrating a first recurrence at 30 minutes and one-sixth showing a first recurrence at 60 minutes. Notably, recovery of PV conduction is more frequently observed in the left superior PV as compared with the other PVs. Therefore reconfirmation of PV isolation after a 30- or even 60-minute waiting period after initial PV isolation or pharmacological provocation with adenosine (up to 30 mg rapid IV bolus) or isoproterenol (up to 20 µg/min IV infusion) has been suggested to improve outcome. Incorporation of shorter waiting time (20 to 30 minutes) in conjunction of adenosine administration can also be reasonable. Of note, each of those methods seems to have unique features in uncovering PV reconnection, and the results of the different methods may not be in agreement. In other words, PV reconnection can potentially be unmasked only after a waiting period but not by administration of adenosine, and vice versa. Even the sites of PV reconnection uncovered

Fig. 15.35 Pulmonary Vein (PV) Isolation During Atrial Fibrillation (AF) Using a Basket Catheter. Bipolar recordings from the eight electrodes (1-2, 3-4, 5-6, 7-8) on each of the eight splines (BA through BH) of the basket catheter positioned in the left superior PV initially show sharp PV potentials. Radiofrequency ablation during AF results in gradual slowing and then disappearance of all PV potentials and persistence of residual low-amplitude, far-field, left atrial (LA) electrograms, consistent with LA-PV entrance block. AF continues in the coronary sinus (CS) recordings.

by one method can be different from those uncovered by the other methods.

The administration of adenosine has been shown to transiently unmask dormant conduction between the PVs and the LA. Activation of adenosine-sensitive potassium channels hyperpolarizes the resting membrane potential of atrial myocytes injured by RF energy and, hence, can potentially restore excitability by removing voltage-dependent sodium current inactivation, facilitating electrical conduction and resulting in transient PV-LA reconnection. Adenosine-mediated dormant conduction can be revealed in up to 53% of patients, and PVs that demonstrated dormant conduction with adenosine are more likely to recover conduction spontaneously after initial isolation. However, studies investigating the implications of adenosine-induced PV reconnection have yielded conflicting results regarding whether adenosine-mediated PV conduction recovery is an independent predictor of AF recurrence, and whether targeting dormant PV conduction provoked by adenosine with additional ablation lesions improves long-term arrhythmia-free outcomes. It is important to note that there is a dose-dependent effect when assessing for dormant PV conduction. Adenosine doses sufficient to induce AV block with at least 1 nonconducted atrial paced beat are likely required to unmask dormant PV conduction (eFig. 15.14). The dose can be gradually escalated until AV block is observed. Alternatively, administering higher doses (e.g., 30 mg IV) from the start can be appropriate.

It is important to note that adenosine testing has several limitations. Because adenosine only reveals PV reconnection transiently, targeting

the precise area of reconnection can be difficult, and evaluating the efficacy of additional ablation lesions is not feasible without repeating adenosine administration. Also, it remains uncertain whether adenosine testing should be repeated to assess separately for both persistent entrance and exit block.^{159,160}

Data suggest that adenosine is superior to isoproterenol for unmasking dormant PV conduction after PV isolation, with no significant additional value of combining the two. Therefore the role of isoproterenol infusion (alone or in conjunction with adenosine) appears limited.

A recent expert consensus statement considered a 20- to 30-minute waiting phase reasonable to incorporate into an AF ablation procedure (class IIa), and that administration of adenosine 20 minutes after initial PV isolation phase may be considered (class IIb).

Inability to Isolate a Pulmonary Vein

More than 90% of PVs can be electrically isolated from the LA by conventional applications of RF energy along segments of the ostia, guided by PV potentials. The inability to abolish the arrhythmogenic PV potential or its recovery (even in a very discrete area and with a prolonged conduction time) is associated with a higher AF recurrence rate.

The inability to disconnect the PV has been demonstrated in 3% to 24% of targeted PVs in previous studies and can be attributable to anatomic variations in the geometry of the ostia that could limit optimal recording of PV potentials with the ring catheter. Using an expandable

B. Adenosine following additional PV isolation

eFig. 15.14 Adenosine Administration Revealing Dormant Pulmonary Vein (PV) Conduction. Surface electrocardiogram and intracardiac recordings from ring catheter (*Lasso*) in left superior PV following PV isolation. (A) The first three stimulated complexes (*S*) show atrial capture with atrioventricular (AV) conduction but no conduction into the PV; commencing with the 4th stimulus, PV conduction is seen (*red arrow*) and continues for another six complexes. A dazzling effect on AV induction is not manifest until two complexes later (*green arrow*). (B) Repeat ablation has been performed and at this time adenosine results in AV block (*green arrow*) but no restoration of PV conduction. *Abl D*, Distal ablation site; *Abl P*, proximal ablation site; *CS*, coronary sinus; *His D*, distal His bundle; *His M*, middle His bundle; *His P*, proximal His bundle.

ring catheter or using ICE to guide positioning of the ring catheter aids in stabilizing the mapping catheter. In addition, some fascicles can be too thick to be ablated with conventional RF energy, and the use of high-power output or an irrigated-tip ablation catheter can be required to isolate those PVs. The inability to isolate a PV also can be caused by the presence of electrical connections between ipsilateral veins (which are observed in approximately 18% of the patients). In these patients, ostial ablation of an untargeted PV is required for successful disconnection of the targeted PV. Occasionally, the proximity of a targeted PV to an important extracardiac structure (esophagus, phrenic nerve) limits the ability to isolate the vein fully.¹⁵⁸

Outcome

Segmental ostial PV isolation represented an important advance in catheter treatment of AF and was found more efficacious than focal ablation for the control of paroxysmal AF. As compared with focal ablation, PV isolation eliminates the need for detailed mapping of spontaneous ectopy, and there is a clear-cut endpoint of ablation, even when spontaneous arrhythmias are absent. Importantly, the risk of PV stenosis is less than that with focal PV ablation.

On the other hand, the benefit of empiric isolation of all PVs over the identification and selective isolation of arrhythmogenic veins is less clear. Previous comparative case series demonstrated that empirical isolation of all PVs led to superior outcomes over isolating fewer veins, which is expected given that most (up to 71%) patients prove to have three or more arrhythmogenic PVs. Nevertheless, in patients with predominantly paroxysmal AF, isolation of arrhythmogenic veins identified using a comprehensive stimulation protocol was found as effective as empiric isolation of all PVs in achieving long-term arrhythmia control after a single ablation procedure, and potentially is associated with shorter fluoroscopy times and fewer adverse events. However, identification of the arrhythmogenic PVs during an EP study remains challenging, laborious, and time consuming.¹⁶¹

Reconnection of previously isolated PVs (caused by recovery of conduction through inadequately ablated fascicles in the muscle sleeves surrounding the PV) is probably the most common reason for recurrent AF after PV isolation, at least among patients with paroxysmal AF. Other causes include ectopy from PVs not targeted or could not be isolated at the initial procedure, and the presence of non-PV triggers. In one study on the recurrence of AF following PV electrical isolation, most triggers were found to originate from previously targeted PVs (54%), whereas one-third of recurrent triggers (32%) originated from PVs that were not ablated during the initial session. Notably, 61% of previously isolated PVs in that series had evidence of recovered PV potentials. Therefore acutely successful PV isolation does not confer permanent disconnection of the PV musculature from the LA, and in most isolated PVs residual conduction remains or recurs with time.

Predictors of early recurrence of AF include older age (65 years or more), the presence of associated cardiovascular disease, the presence of multiple AF foci, the presence of AF foci from LA free wall, LA enlargement, and longstanding persistent AF. Predictors of late recurrence of AF include the presence of early recurrence of AF and the presence of multiple AF foci.

In most reports, a successful outcome was defined as the absence of any symptomatic atrial arrhythmias beyond the first 2 to 3 months after ablation without the use of antiarrhythmic drugs. Medium-term success has reportedly been achieved in up to 70% of patients with paroxysmal AF but in only 30% of patients with persistent AF. This finding suggests that intervention with PV isolation in patients with drug-refractory paroxysmal AF should not be postponed until the AF becomes persistent. Once AF has become persistent, it is likely that PV

isolation will have to be supplemented by some other type of ablation procedure directed at the atrial myocardium. The less satisfactory outcome of PV isolation in persistent AF suggests that the PVs play a less critical role in generating AF once the AF has become persistent. It is possible that the EP and anatomic remodeling that occurs during persistent AF often allows the atria to continue fibrillating independently of the PVs. The overall major complication rate is 6.3%, including stroke (0.7%), cardiac tamponade (1.2%), and significant PV stenosis (4.3%).

CIRCUMFERENTIAL ANTRAL PULMONARY VEIN ISOLATION

Rationale

The muscular sleeves of the PVs extend proximally to the antral-LA junction and are not restricted to the tubular portion of the PV. This finding is not surprising because embryologically the PVs originate from the posterior LA wall, so that a continuum exists between the atrial wall and PVs. Therefore it is likely that the PV antrum also has an arrhythmogenic potential similar to that of the tubular portion of the PVs. Furthermore, the PV antrum can potentially harbor ganglionated plexuses that have been implicated in the genesis of AF, as well as high-frequency activity or rotors that are thought to have anchor points necessary for perpetuation of AF. Hence, ablation at the antrum not only is effective to isolate PVs electrically, but also it can eliminate other potential mechanisms of AF. In addition, a large area of the posterior LA is included inside the ablation lines and a considerable amount of atrial debulking (approximately 25% to 30%) may occur after antral PV isolation.

Circumferential antral PV isolation has several additional advantages over segmental ostial PV isolation. This technique does not rely on localizing the sites of electrical breakthroughs into the PV, and thus it is easier to perform during AF. Furthermore, this approach reduces the risk of PV stenosis because ablation is performed in the LA, away from the PV ostia (Fig. 15.36). In addition, in some patients with PV anatomic variations, this approach can be more favorable. One such variation is the presence of a common ostium of the left PVs, occurring in up to 32% of patients undergoing PV isolation. Such common ostia typically are too large to allow a stable position of the ring catheter. Another anatomic variation is the presence of a right middle PV, present in up to 21% of patients, which typically is separated from the right superior PV and right inferior PV by a narrow rim of atrial tissue. This would predispose to sliding of the ablation catheter into the PV during ablation. Another anatomic finding that renders extraostial PV isolation more favorable is a PV ostial diameter of less than 10 mm. RF application at a small ostium carries a higher risk of PV stenosis.

Circumferential antral PV isolation has been shown to be more effective in preventing AF recurrence than segmental ostial PV isolation, and this procedure has become a preferred ablation strategy in patients with paroxysmal and persistent AF. The preferred ablation target is the outmost atrial side of the PV ostium.¹⁰

Identification of Pulmonary Vein Antra

The objective of the mapping and ablation procedure is to identify PV potentials along the perimeter of the PV antrum and ablate to eliminate these potentials completely. Reliable definition of the anatomy of PV antra is crucial to provide an effective set of lesions. A navigation system is used to provide 3-D anatomic images that allow safe maneuvering of the ablation catheter to complete the lesions at the antrum and eliminate conduction to PVs. However, the use of these systems does not replace circumferential PV mapping and an EP endpoint to the procedure.

Fig. 15.36 Circumferential Antral Electrical Isolation of the Pulmonary Veins (PVs). Segmented three-dimensional computed tomography scan of the left atrium (LA) and PVs shown in posteroanterior (A), right lateral (B), and left lateral (C) views. Contiguous radiofrequency lesions are deployed (*white dots*) in the LA proximal to the ostia of the PVs, creating a circumferential line around each of the right-sided PV ostia. The left-sided PVs share a large common ostium, and en bloc encirclement of those ostia is performed. LAA, LA appendage; LIPV, left inferior PV; LSPV, left superior PV; RIPV, right inferior PV; RSPV, right superior PV.

Ring Catheter Mapping

The ring catheter is used for circumferential ostial mapping of PV potentials, as described for segmental ostial PV isolation. However, the breakthrough segments (electrical connections) connecting the LA to the PV, identified as the earliest PV potentials recorded from the ring catheter, are not specifically mapped or targeted. Instead, the entire perimeter of the PV ostium is the target for the ablation procedure. Using the ring catheter enables circumferential mapping of the PV ostia perpendicular to the axis of the vein and serves as a landmark for the PV ostium around which RF lesions are delivered. In addition, the ring catheter is vital for confirming complete electrical isolation of the PV, an important endpoint of this ablation strategy.

Basket Catheter Mapping

The technique of positioning the basket catheter into the PVs was described earlier in this chapter (see [eFig. 15.11](#)). For antral PV isolation, the basket catheter is introduced toward the distal PV under fluoroscopy guidance and then is pulled back as proximally as possible without dislodgment until its most proximal electrodes are positioned at the PV antrum, which is identified by selective angiography. The basket catheter can help identify the true junction between the PVs and LA anatomically and electrically. Because the basket catheter conforms to the shape of the PV, it provides information about the anatomy of the PV.

Furthermore, longitudinal mapping with a basket catheter can help identify the transition zone between the PV and LA potentials. Far-field LA potentials are normally recorded almost simultaneously all over the PV, whereas the activation sequence of the PV potentials is from proximal to distal when the activation propagates from the LA to the distal PV. Consequently, the interval between the LA potentials and PV potentials is shorter at the proximal PV than at the distal PV. At the transition zone, total fusion of the PV and LA potentials occurs ([eFig. 15.15](#)). Therefore the potential recorded at the transition zone may reflect the activation of the PV antrum. A transverse activation pattern, indicated by simultaneous activation recorded by some neighboring electrode pairs along the spline, sometimes occurs around the LA-PV junction before the longitudinal activation pattern within the PVs. This pattern may reflect the activation of the circle of myocardium at the PV antrum.

On the basis of these findings, PV antrum potentials are defined as single sharp potentials formed by the total fusion of the PV and LA

potentials around the PV ostium or single sharp potentials with a transverse activation pattern around the PV ostium (see [eFig. 15.15](#)). Targeting those potentials by RF ablation would target the transition zone between the PV ostium and LA. When potentials conforming to the definition of PV antrum potentials are observed from some electrode pairs on the same spline, the antrum potential recorded from the most proximal electrode pair is targeted. RF applications are also delivered to the gap between the targeted electrode pairs on the neighboring splines to produce a continuous RF lesion at the PV antrum.

Electroanatomic Mapping

Different navigation tools, including the EnSite NavX, CARTO, and Rhythmia systems, have been used to facilitate circumferential PV isolation. These systems can provide a high-resolution reconstruction of the LA and defining PV ostia and antra and allow real-time visualization of the ablation catheter within the reconstructed 3-D geometry (see [Fig. 6.3](#)). In addition, ablation lesions can be tagged, thus facilitating creation of lines of block with considerable accuracy by serial RF lesion placement and allowing verification of the continuity of ablation line.

Using either the CARTO or NavX system, the 3-D shell representing the LA and PVs is constructed using the ablation or ring catheter, or both. With the Rhythmia system, the mini-basket array catheter (Orion, Boston Scientific) is used to construct the anatomic shell. To acquire the PVs, entry into the vein is clearly identified as the catheter leaves the cardiac shadow on fluoroscopy, the impedance usually rises to more than 140 to 150 Ω , and electrical activity disappears. Because of the orientation of some veins and the limitations of catheter shape, it can be difficult to enter deeply into some veins, but the impedance still rises when the catheter is in the mouth of the vein. To differentiate between PVs and LA more clearly, voltage criteria (fractionation of local bipolar electrogram) and impedance (rise more than 4 Ω higher than the mean LA impedance) can be used to define the PV ostium. Mapping of each PV is performed by placing the mapping catheter 2 to 4 cm inside the PV and slowly pulling it back to the LA under fluoroscopic or electroanatomic mapping guidance. Care should be taken to reconstruct each PV ostium and the transition toward the LA (antrum), posterior free wall, mitral isthmus, and left interatrial septum. Subsequently, the system is allowed to create the geometry automatically while the ablation (or ring) catheter is moved throughout the LA. Sequential positioning of a catheter at multiple sites along the endocardial surface of the LA establishes that chamber's geometry.

eFig. 15.15 Identification of the Pulmonary Vein (PV) Antrum Using the Basket Catheter. The basket catheter is positioned in the left superior PV. Shown are seven bipolar recordings obtained from the eight electrodes (1-2, 2-3, to 7-8) on one of the eight splines (B₁₋₂ through B₇₋₈) of the basket catheter. During coronary sinus pacing, far-field left atrial (LA) potentials are normally recorded almost simultaneously all over the PV (*shaded area*). In contrast, PV activation propagates from proximal (ostial) to distal, and the interval between the LA potentials and the PV potentials is shorter at the proximal PV than at the distal PV. At the transition zone (PV antrum), a total fusion of the PV and LA potentials occurs (B₇₋₈).

The ring catheter is used for mapping PV potentials in conjunction with EnSite or CARTO electroanatomic mapping systems; the mini-basket catheter (Orion) is used for form mapping in conjunction with Rhythmia (Fig. 15.37).

Computed Tomography and Magnetic Resonance Imaging

CMR and CT provide critical information regarding the number, location, and size of PVs, as needed for planning the ablation and selecting appropriately sized ablation devices. Resulting images also identify branching patterns of potentially arrhythmogenic PVs, disclose the presence of fused superior and inferior veins into antral structures, and clarify the potentially confounding origins of far-field electrograms that masquerade as PV potentials.

Furthermore, the segmented CT/CMR volumes can be downloaded on the electroanatomic mapping system platforms. The 3-D electroanatomic maps can be simultaneously displayed side-by-side with CT/CMR segmented cardiac scans to confirm cardiac structures and guide ablation. These systems also enable registration of the preacquired 3-D CT/CMR images of LA reconstructions on the real-time 3-D electroanatomic maps reconstructed from multiple endocardial locations. This allows real-time visualization of the location and orientation of the catheter tip within the registered CT/CMR anatomic framework (see Fig. 6.3). The process of image integration—preprocedural CT and CMR image acquisition, image segmentation and extraction, and image registration—is discussed in Chapter 6.

Intracardiac Echocardiography

Phased-array ICE has been used in AF ablation procedures for several purposes: to assist with transseptal puncture, to identify the number and position of PVs, to identify the true border of the PV antrum, to determine the branching patterns of the right PVs needed for total PV isolation, to guide the positioning of the ring and ablation catheters at the antrum of the PV, to verify ablation catheter tip to tissue contact, to assess the degree of PV occlusion during balloon-based ablative interventions, and to detect procedural complications (e.g., pericardial effusion, LA thrombus, and PV stenosis).

For ICE imaging, a 10 or 8 Fr 64-element phased-array ultrasound catheter is positioned in the middle of the RA via an 11 or 9 Fr left femoral venous access. The ICE catheter remains in the RA for the entire procedure to guide transseptal puncture, define PV anatomy, and monitor for microbubble formation during RF ablation. A 7.5- or 8.5-MHz imaging frequency optimizes visualization of LA structures and PVs beyond the interatrial septum. PV imaging is uniformly possible by first visualizing the membranous fossa from a middle to low RA catheter tip position. From this view, clockwise catheter rotation allows visualization of the LAA, followed by long-axis views of the left superior and inferior PVs (see Figs. 4.11 and 6.32). Further clockwise rotation of the catheter brings the orifice of the right superior and inferior PVs into view. The LA ostia of these veins are typically viewed en face, to yield an owl's eye appearance at the vein's orifice.

As the operator images each vein, the ring and ablation catheters can be positioned at the antral-LA interface for ablation. Because the PV antrum is a large-diameter structure, its circumference cannot be mapped using a stationary ring catheter fixed in one position. Instead, the ring catheter must be sequentially positioned along each segment of the antral circumference to look for PV potentials. ICE can identify the true border of the PV antrum and guide positioning of the ring and ablation catheters. Therefore the ring catheter is a roving catheter in this procedure. An operator's assistant often must hold the ring catheter in position around the antrum for stability. When mapping the anterior segments of the left PVs or septal segments of the right

PVs, the ring catheter must be advanced slightly because of the oblique nature of the antral-LA interface.

In addition, ICE can help with the registration process of the CT/CMR image with the electroanatomic mapping system. Furthermore, the CARTOSound Image Integration Module (Biosense Webster) allows incorporating a real-time ICE volume map of the LA and PVs with the electroanatomic map, either as a stand-alone tool to guide navigation and ablation or as a facilitator of CT/CMR image integration (see Chapter 6). Overall accuracy in the LA and PV anatomic reconstruction using the CARTO fast anatomic mapping (FAM) module was found to be superior to the ICE-guided approach. ICE-derived anatomic reconstruction often yields a significant underestimate of true dimensions of both LA and PV when ultrasound exploration is performed by placing the ICE catheter in the RA only. Hence, ablation points fall beyond the 3-D ICE-derived surface contour more often than when guided by FAM or merged 3-D ICE-CT volume rendering. This limitation can potentially be overcome by placing the ICE catheter in the CS, in the RV, or directly in the LA, but a more extensive approach is time consuming and can increase complications. Nevertheless, ICE-derived mapping techniques reduce both fluoroscopy time and the time spent in the LA. Furthermore, the ICE direct visualization of distinct anatomic structures allows a good alignment with CT/CMR and makes this technique suitable for integration processes. On the other hand, FAM allows a more accurate rendering of both LA and PV, which can potentially replace the need for preacquired CT/CMR.^{162,163}

Target of Ablation

The ablation procedure is based on electrical isolation of all PVs. The objective is to identify PV potentials along the circumference of the PV antrum and ablate to eliminate these potentials completely. However, unlike segmental ostial PV isolation, the ostial portions of the breakthrough segments (electrical connections) connecting the LA to the PV (identified as the earliest PV potentials recorded from the ring catheter) are not the sole target of ablation. Complete encirclement of each PV antrum with ablation lesions is the goal of the ablation procedure, which would consequently result in PV isolation (see Fig. 15.36). All PVs are targeted.

Ablation lines consist of contiguous focal lesions deployed in the LA at a distance exceeding 5 mm proximal to the ostia of the PVs, to create a circumferential line of conduction block around each PV.¹⁶⁴ PV isolation is performed 10 mm or more from the ostium of the right PVs, as well as for the posterior and superior aspects of the left PVs, to enhance efficacy and prevent PV stenosis. However, ablation at the anterior portions of the left PVs usually requires energy be delivered less than 5 mm from the ostium of the PV to achieve catheter stability. Wider ablation lines encircling the entire PV antrum and encompassing a larger size of the LA isolated surface area can potentially improve long-term ablation outcome.

When two or three ipsilateral PV ostia are coalescent, en bloc encirclement of those ostia is performed (i.e., one encirclement for the right-sided PVs or one encirclement for the left-sided PVs), and no ablation line between the ipsilateral PVs is deployed (see Fig. 15.36). Importantly, single encirclement of ipsilateral PVs predisposes to breakthrough conduction of both ipsilateral PVs in case of a single gap in the en bloc circle. Furthermore, one report found that AF triggers originate frequently from the carina region of the PVs; hence, ablation in this area between ipsilateral PVs can be effective for targeting the source of the PV triggers. Of note, ablation along the ridge between ipsilateral PVs is frequently necessary to achieve complete electrical isolation of the PVs despite an apparently complete circumferential antral ablation ring.

Acute PV electrical isolation often can be achieved before anatomic completion of the RF ablation line encircling the PV antrum. However,

Fig. 15.37 Pulmonary Vein (PV) Isolation Using the Mini-Basket Catheter (Orion). (A) Fluoroscopy (right anterior oblique view) of the Orion catheter (*arrowheads*) positioned at the ostium of the left superior PV. Also shown are the Halo catheter (positioned in the right atrium around the tricuspid annulus), the ablation (*Abl*) catheter, and the coronary sinus (*CS*) catheter. (B) Intracardiac echocardiography (ICE) showing the Orion catheter (*arrowheads*) positioned at the ostium of the left superior PV. (C–E) Surface electrocardiogram and intracardiac bipolar recordings obtained from the electrodes 2-3, 4-5, and 6-7, on each of the eight splines (A through H) of the mini-basket catheter. Circumferential antral PV isolation was performed during CS pacing using radiofrequency energy. At baseline (C), PV potentials recorded by the mini-basket catheter are prominent (encased in the *white rectangle*). After ablation of part of the PV circumference (D), PV potentials are eliminated. Ablation around the entire circumference of the PV antrum (E) results in complete elimination of PV potentials on all splines of the mini-basket catheter. In addition, spontaneous PV ectopy (*blue rectangle*) is observed, and is dissociated from the left atrium (LA).

it is likely that reversible tissue injury caused by tissue stunning, edema, ischemia affecting the unablated tissue within the gaps in the incomplete ablation line. It is important to recognize that unlike segmental ostial PV isolation, whereby complete electrical isolation of the PV can be achieved with noncontiguous ablation line along the PV ostium targeting individual PV muscular sleeves, a noncontiguous ablation line during circumferential antral ablation is unlikely to produce durable PV isolation; electrical reconnection can occur once the unablated PV muscular sleeves recover from the transient injury. As such, initial development of PV entrance and exit block is not a sufficient endpoint for ablation when it occurs with incomplete circumferential antral PV ablation line. Anatomic completion of the circumferential ablation line by contiguous, high-quality RF ablation lesions is required to improve long-term durability of PV isolation.¹⁶⁵

Ablation Technique

Several ablation technologies have been used for circumferential PV isolation. Most commonly, RF ablation is performed with an irrigated-tip ablation catheter. Alternatively, an 8-mm-tip standard ablation catheter can be used. Technological evolution is now aimed at developing new catheter designs for circumferential ablation of the PVs as an alternative for the conventional point-by-point RF ablation. Currently, two multielectrode circumferential catheter systems are undergoing clinical evaluation: The PV ablation catheter (PVAC, Medtronic, Minneapolis, MN, United States) and the nMARC system (Biosense Webster) (see **Chapter 7; Figs. 7.11 and 7.12**).

Furthermore, balloon-based ablation devices using different energy sources (e.g., cryothermal energy, laser energy, RF, and high-intensity focused ultrasound [HIFU]) have been evaluated. The cryoballoon (Arctic Front, Medtronic) and laser balloon (Heartlight, CardioFocus, Marlborough, MA, United States) catheters have proven feasibility, safety, and efficacy in the treatment of AF. Because of severe complications in the form of atrioesophageal fistula, the HIFU balloon is no longer in clinical use (see **Chapter 7**). The clinical evaluation of the RF balloon catheter (Hot Balloon Catheter, Hayama Arrhythmia Institute, Kanagawa, Japan) is still in its initial stages.

Conventional Radiofrequency Ablation

Ablation is started at the posterior wall of each PV, usually fluoroscopically facing the border of the spine in the anteroposterior projection, and continued around the venous perimeter. With the catheter tip at the PV ostium, the posterior wall of the right PV is reached by counterclockwise torque of the catheter and the left PV by clockwise torque. For ablation at the anterior portions of the left PVs, energy must usually be delivered within a few millimeters of the vein (because of a relatively narrow border between the left PVs and the LAA, and the difficulty to balance the catheter tip on the narrow rim of tissue separating these structures) to achieve effective disconnection. Ablation on the venous aspect of the ridge is commonly performed for simplicity; ablation on the LAA side is feasible, but the RF energy must ablate tissue on the posterior wall of the appendage as well as the anterior wall of the PV, so it is more difficult. Sites of RF energy delivery are tagged on the reconstructed 3-D map. This tagging helps ensure coalescence of the ablation lesions to ensure continuity of the ablation line, assuming ablation at each site has been effective (see **Fig. 15.36**).¹⁶⁴

Open irrigation RF catheters are preferred for AF ablation. RF power output has a significant impact on the efficacy and safety of catheter ablation for AF. The optimal power output associated with the best balance between safety and efficacy outcomes appears generically to range between 25 and 45 W. Higher power output at shorter duration (15 to 20 seconds) also appears safe and efficacious. Titration of power output with real-time visualization of microbubbles by ICE (down

titrating by 5 W upon appearance of microbubbles) rather than fixed or limited empirical settings of power output during RF ablation appears to be beneficial.¹⁶⁶

Using an irrigated-tip catheter, power output is limited to 25 to 30 W (or even less) on the LA posterior wall (where the atrial wall is thin and esophageal proximity presents potential danger), and to 30 to 50 W on the left PV-LAA ridge and anterior LA wall, and a target temperature of less than 43°C and irrigation rates of 5 to 20 mL/min (0.9% heparinized saline). Some evidence indicates that ablation over the thin posterior wall, especially near the esophagus, can be performed with lower power as well as low irrigation rates (since irrigation fundamentally allows greater power delivery to deeper tissue, which is not desirable on the posterior wall). Less often, ablation is performed using an 8-mm-tip conventional ablation catheter, with a maximum power of up to 70 W and a target temperature of 50°C to 55°C.

RF energy is delivered for 30 to 60 seconds at each point, until the maximal local electrogram amplitude is decreased by 50% to 90% or double potentials are observed or to achieve an impedance drop of 5 to 10 Ω at the ablation site. RF application can be prolonged for 1 to 2 minutes when a change occurs in the activation or morphology of the PV potentials, as determined by circumferential mapping recorded downstream on the ring catheter. Typically, PV potentials become progressively delayed until disappearing entirely (or showing dissociated firing). If PV potentials remain after completion of ipsilateral circumferential ablation, additional RF applications targeting earliest residual potentials can be performed.

Alternatively, short RF applications (for 2 to 5 seconds) at a higher power (50 W, irrigation rate 30 mL/min, maximum temperature 43°C) can be employed. The latter approach results in momentarily higher LA tissue temperatures and allows the tip to be set at a high power to injure the superficial tissue while minimizing time-dependent deep heating through excessive heat transfer. Typically, the ablation catheter is dragged continuously in small increments every 2 to 5 seconds during continuous RF delivery, and ablation is repeated at each site, if required, for many times throughout the procedure until the local atrial electrogram is completely eliminated. It is probably reasonable to allow at least 2-minute time intervals before returning to ablate a previously ablated site to allow for heat dissipation, especially when ablating at the LA posterior wall, to avoid excessive esophageal heating.

Adequate and stable catheter tip-tissue contact is critical to ensure effective and permanent ablation lesions. The use of steerable transseptal sheaths facilitates more stable catheter positioning and access to all desired ablation targets for PV isolation. In addition, ICE can provide detailed anatomic information and real-time information of the location of the tip electrode of the ablation catheter and can help confirm catheter stability. Real-time measurements of the contact force of the ablation tip have been introduced using different technologies (see **Chapter 7; see Fig. 7.8**). Using a force-sensing RF catheter (with a minimum targeted contact force of 5 to 10 g) is recommended.

Cryoballoon Ablation

The cryothermal balloon ablation system (Arctic Front, Medtronic) consists of a nondeflectable, 10.5 Fr catheter with distally mounted coaxial double inner-outer cooling balloons ("balloon within a balloon," outer balloon maximum diameter, 23 or 28 mm) (see **Fig. 7.15**). The refrigerant nitrous oxide (N_2O) is delivered under pressure from the console into the inner balloon chamber via a lumen within 2 mm of the catheter tip, where it absorbs heat energy as it undergoes liquid-to-gas phase change, resulting in inner balloon cooling to temperatures of -80°C or lower. During cryotherapy, temperature is monitored via a thermocouple located at the inner balloon. The balloon catheter is delivered to the LA via a 15 Fr deflectable sheath with a 12 Fr inner

lumen (FlexCath; Medtronic). A small-caliber octapolar circular mapping catheter (Achieve, Medtronic) passes through the central lumen of the cryoballoon, allowing real-time PV mapping during cryoablation and also providing central luminal support (instead of a guidewire).

Positioning the cryoballoon. Transseptal LA access is obtained using a standard transseptal sheath. A low anterior transseptal puncture site (at the lower third of the septum and anterior reach at the plane of ICE where the mitral valve is in view) is recommended to allow more space for the balloon to be rotated posteriorly to the right inferior PV. The delivery sheath (FlexCath) for cryoballoon catheter is then exchanged over a long stiff guidewire extended into the left superior PV.

Selection of cryoballoon size (23 vs. 28 mm) is based on PV size using preacquired CT/CMR, PV angiography, or TEE. However, whenever possible, the larger diameter cryoballoon is preferred since it is associated more proximal (antral) location of the circumferential ablation lesions as well as lesser risk of phrenic nerve injury during applications to the right PVs.

The deflated cryoballoon is inserted into the steerable delivery sheath and advanced over either an extra-stiff 0.032-mm guidewire or the Achieve catheter. The mapping catheter should always lead the cryoballoon catheter to prevent trauma from the stiffer cryoballoon catheter tip. Also, when maneuvering the sheath to the desired PV, the balloon with the soft-tipped mapping catheter should always lead the sheath to avoid sheath trauma in the LA or PV.¹⁶⁷

The mapping catheter is navigated into each of the PVs under fluoroscopy of ICE guidance and is advanced deep into the target PV. The deflated cryoballoon catheter is then advanced outside the sheath toward the PV ostium over the mapping catheter. Once in position at the PV antrum, the cryoballoon is inflated (outside of the PV, to avoid any mechanical damage) and then is advanced into the PV to occlude the vein.

Assessment of PV occlusion. Once the cryoballoon is inflated at the PV antrum, complete occlusion of the PV with the cryoballoon should be verified. Efficient cryoablation and PV electrical isolation requires adequate contact and seal of the cryoballoon over the PV ostium. Adequate contact is important in creating a complete circumferential PV lesion without gaps. Adequate seal prevents blood flow around the balloon during freezing, which otherwise can limit tissue cooling and impair lesion formation because of convective warming.

PV occlusion can be assessed by selective PV angiography, analysis of the PV pressure waveform, as well as ICE. Complete PV occlusion is confirmed by contrast injection into the distal lumen of the cryoballoon showing total contrast retention with no backflow to the LA (eFig. 15.16). Also, the disappearance of flow on color Doppler obtained by ICE or TEE can help confirm complete PV occlusion (Fig. 15.38). In addition, PV occlusion can be assessed by analysis of the PV pressure waveform (recorded through the central lumen of the balloon catheter), although the accuracy of this method is still debated. Normally, intra-PV pressure tracing is similar to that of the LA. During NSR, the LA pressure waveform displays a small A (atrial) wave and a large V (ventricular) wave. In AF, the A wave is absent. Upon PV antral occlusion by the cryoballoon, intra-PV pressure tracing measured via the inner lumen of the balloon catheter changes to a wedged PV tracing with loss of the A wave (during NSR) and an increase in the slope and amplitude of the V wave (Fig. 15.39).¹⁶⁸

If PV occlusion is not achieved, the device can be turned clockwise and counterclockwise or even slightly withdrawn until PV flow disappears. Also, the guidewire (or mapping catheter) can be positioned in a different PV branch to change the orientation of the balloon at the PV ostium (see eFig. 15.16). Also, applying forward pressure and advancing the sheath against the proximal hemisphere of the balloon can

provide support for better PV occlusion. Among the other maneuvers used to facilitate PV occlusion by the cryoballoon is the “hockey stick technique,” which helps optimize tissue contact at the inferior circumference of the inferior PVs. This technique involves advancing the sheath (with the mapping catheter or guidewire placed in the PV with a maximal bend to the superoposterior LA) and pushing the balloon into the inferior part of the PV ostium. The “pull-down technique” is used if angiography indicates perfect contact of the balloon only at the superior circumference of the PV but not at the lower PV circumference. The pull-down involves waiting for the balloon to adhere to the superior aspect of the targeted vein (generally after 60 seconds), followed by catheter and shaft deflection to pull the frozen balloon downward to achieve contact with the inferior portion of the vein and thereby eliminate the inferior gap. If complete occlusion cannot be achieved, separate energy applications can be delivered after adjustment of the balloon angle of engagement to ensure complete encirclement of the PV antrum.¹⁶⁷

If no leak around the balloon is visible on venogram, the cryoballoon is slightly withdrawn to allow a leak around the PV–balloon interface to better define the PV ostium and ensure that the balloon is not seated inside the PV (the “proximal-seal” technique). The balloon is then gently pushed to regain PV occlusion.¹⁶⁷

If antral occlusion of a left common PV could not be obtained, a sequential ablation approach is employed, targeting the superior branch of the left common PV followed by ablation of the inferior branch, thus accepting rather distal ablation without treatment of the antral aspect of the left common PV.^{169,170}

Mapping PV potentials. Once PV occlusion is optimized, the Achieve mapping catheter is repositioned as proximal to the PV ostium as possible (without compromising the degree of pulmonary venous occlusion) to record PV potentials. However, due to its small caliber, the Achieve catheter rarely achieves true circumferential contact with the PV ostium (leading to PV potentials being recorded on only a portion of the bipoles) and it often lacks the mechanical support needed for adequate mapping of the PV ostia. Furthermore, distal positioning of the mapping catheter within the PV can be necessary to optimize cryoballoon-PV antrum contact (eFig. 15.16). In the latter setting, repositioning of the mapping catheter can be attempted immediately (within 10 seconds) after initiation of a freezing cycle. After about 15 seconds into the freezing cycle, the central lumen is frozen, and the wire cannot be moved.^{167,171}

Not infrequently, adequate PV potential recording using the Achieve mapping catheter is not feasible when the cryoballoon is in position. Therefore the PV ostia must be carefully mapped before and after the cryoablation lesion has been delivered in order to verify electrical PV isolation. This can be performed using the Achieve catheter or using a separate conventional circular mapping catheter (e.g., Lasso catheter) introduced into the LA through the same transseptal sheath as the cryoballoon (before and after cryotherapy) or through a second transseptal sheath.^{167,171}

Cryoenergy application. After confirmation of adequate PV antral seal, cryoenergy is applied. Each cryoenergy application is extended for 180 seconds, with a maximum of 1 bonus application after the attainment of PV isolation. During freezing, maneuvering the cryoballoon should be avoided as it can cause mechanical tissue damage due to cryo-adhesion of the balloon to the endocardial wall. Once the freeze application stops, the balloon and tissue interface should be allowed to thaw and temperature reach 35°C before moving the cryoballoon.¹⁶⁷

Several parameters are monitored during cryoapplication, including the time-temperature curve (Fig. 15.40), the nadir balloon temperature achieved, ablation effects on PV potentials recorded by the Achieve mapping catheter, as well as esophageal luminal temperature (with the

eFig. 15.16 Pulmonary Vein (PV) Angiography to Assess Venous Occlusion by the Cryoballoon. The cryoballoon catheter (*blue arrows*) is inflated and positioned at the ostium of the left superior PV. (A) Angiography of the PV (right oblique view) is performed by injection of contrast into the distal lumen of the cryoballoon shows small leak at the inferior aspect of the PV ostium (*yellow arrows*). (B) The Achieve mapping catheter (*arrowheads*) is advanced into a different branch of the PV to change the orientation of the balloon at the PV ostium, and now no leak around the balloon is visible on venogram. CS, Coronary sinus.

(A) Color Doppler reveals flow (green arrows) at the inferior aspect of the balloon consistent with flow from the nearby left inferior PV. (B) Color Doppler reveals flow (green arrows) at the inferior aspect of the balloon consistent with leak from the left superior PV itself, indicating incomplete PV occlusion.

Fig. 15.39 Assessment of Pulmonary Vein (PV) Occlusion by Analysis of PV Pressure Waveform. The cryoballoon is positioned at the antrum of the left superior PV. The intra-PV pressure waveform is recorded through the inner lumen of the cryoballoon catheter. (A) Cryoballoon PV isolation is performed during sinus rhythm. Before complete PV occlusion (at left), the intra-PV pressure tracing is similar to that of the left atrium, with a small A (atrial) wave and a large V (ventricular) wave. Upon PV antral occlusion by the cryoballoon (at right), the intra-PV pressure tracing changes to a wedged PV tracing with a large V wave and disappearance of the A wave. (B) Cryoballoon PV isolation is performed during atrial fibrillation. At baseline, before PV occlusion (at left), no A waves can be visualized during atrial fibrillation. Upon PV antral occlusion by the cryoballoon (at right), the intra-PV pressure tracing displays an increase in the slope and amplitude of the V wave.

esophageal temperature probe positioned as close as possible to the inflated cryoballoon).

Several intraprocedural cryoablation data can serve as indirect indicators of satisfactory PV occlusion, efficient cryoablation lesion, and durable of PV isolation. These include: (1) fast cooling rate during cryoablation (the achievement of -40°C within 60 seconds); (2) the achievement of nadir temperature of -51°C or colder; and (3) time-to-PV isolation during freezing of 60 seconds or less (and preferably less than 43 seconds). A bonus freeze often is delivered when the cooling

rate is relatively slow (i.e., does not attain -40°C within 60 seconds) or the time-to-PV isolation during freezing exceeds 60 seconds.¹⁷²

The delivery of cryotherapy is aborted if (1) the PV is not isolated within 90 seconds; (2) the temperature fails to descend to -40°C ; (3) any warning signs of phrenic nerve injury are observed; or (4) luminal esophageal temperature lower than 12°C to 15°C . The balloon is then repositioned before another application. In addition, a steep and rapid descent in temperature (colder than -40°C at 30 seconds) and nadir temperatures of -55 to -60°C are potential indicators of a distal (rather

Fig. 15.40 Time-Temperature Curve During Cryoballoon Ablation. During the first cryoapplication (*top*), the cooling rate is relatively slow (as indicated by the slow descent of the balloon temperature and the longer time interval to achieve a balloon temperature of -40°C [double head green arrow]) and the nadir temperature achieved is only -41°C . In contrast, the cooling rate is faster and nadir temperature achieved (-54°C) is colder during the second cryoapplication (*bottom*).

than antral) cryoballoon location within the PV (with consequent reduced exposure of the balloon surface area to circulating blood in the atria and, hence, limited convective warming effects of blood flow), and should prompt cessation of cryoenergy delivery. Placement of the balloon deep inside the PV should be avoided because it can lead to increased freezing area and greater ice formation, which can potentially increase the risk of PV stenosis as well as injury to adjacent extracardiac structures (such as the esophagus and phrenic nerve).^{167,173}

After one or two freezing cycles, the balloon is deflated, and the circular mapping catheter is inserted into the PV to assess for isolation. If PV isolation is not achieved, the cryoballoon is repositioned, and additional freezes are applied. If remnant ostial potentials are still recorded, electrical isolation is segmentally completed by focal cryoablation using an 8-mm cryoablation catheter or by RF ablation.¹⁷⁴

Prevention of phrenic nerve injury. Before engagement of right-sided PVs with the cryoballoon, continuous phrenic nerve pacing is performed (at a PCL of 1000 to 1200 milliseconds, at twice capture threshold) using a diagnostic catheter positioned in the SVC, above level of the cryoballoon. When the procedure is performed under general anesthesia, it is important to avoid paralytic agents or use short-acting paralytic agents only at the time intubation and allow sufficient time for the paralytic effect to fade away before ablation or use a reversal agent (e.g., neostigmine).^{175,176}

Successful capture of the phrenic nerve is confirmed when contraction of the right hemidiaphragm can be observed both under

fluoroscopy or ICE and with manual palpation of the right subcostal region. Phrenic nerve capture can also be monitored by diaphragmatic electromyography (see Chapter 32).^{175,176}

Once the cryoballoon is inflated and just before starting cryoenergy application, optimal phrenic nerve capture and compound motor activation potential (CMAP) amplitude are determined again because the PV ostial geometry and relationship with the phrenic nerve can be altered by balloon inflation. Then, phrenic nerve pacing is started when the freezing temperature reaches -20°C (to avoid balloon dislodgment due to diaphragmatic contraction in the first phase of cryoenergy application). Pacing is continued throughout the whole duration of the cryoenergy application.

The freeze should be immediately aborted if diaphragmatic excursion (on palpation, fluoroscopy, or ICE) becomes less vigorous or ceases or if the maximal diaphragmatic CMAP amplitude is reduced by more than 30% from baseline (see Fig. 32.6). A decrease in diaphragmatic CMAP amplitude is the earliest sign of detectable injury to the phrenic nerve; studies showed that a 30% reduction in diaphragmatic CMAP amplitude presaged impending hemidiaphragmatic paralysis by approximately 30 seconds, making it a valuable method for monitoring phrenic nerve function.

An immediate balloon deflation technique can also be used to help reduce the extent of phrenic nerve injury. While stopping the flow of refrigerant to the balloon allows passive balloon rewarming, balloon deflation and subsequent warming can be delayed. Because the balloon temperature must reach $+20^{\circ}\text{C}$ to allow balloon deflation, continued venous occlusion can slow the passive rewarming process, further prolonging the period of cold-induced injury. An alternate procedure involves forced deflation of the balloon without waiting for rewarming to occur. For this, the stop button on the console is pressed, which halts the refrigerant flow, and 2 seconds later the button is pressed a second time, which causes the pump to apply a vacuum to the balloon, causing immediate deflation. Immediate balloon deflation removes obstruction to blood flow, accelerating tissue rewarming, and helps retract the PV wall away from the phrenic nerve. Although the cryoballoon adheres strongly to tissue during freezing, this adherence is indirect; the balloon adheres to the ice shell, which in turn adheres to the tissue. During immediate balloon deflation, the balloon separates cleanly from the ice shell but the ice shell-tissue interface remains intact.^{177,178}

Advantages. Cryoablation offers several potential advantages over RF ablation, including elimination of the risk of coagulum formation (which should reduce stroke risk), and absence of coagulative necrosis of the ablated tissue (which can potentially reduce the risk of tamponade, PV stenosis, and pericarditis). Although the highly variable anatomy of the PVs provides a significant challenge for any balloon-based technology (it requires the shaft of the catheter to be directed coaxially to the PV), the cryothermal balloon overcomes this problem because the entire balloon can freeze and adhere to the adjacent tissue. As such, the perimeter of the balloon in closest apposition to the vein becomes the source of ablation, irrespective of the orientation in the vein. Also, compared with other balloon-based ablation technologies (HIFU and endoscopic laser), the cryoballoon is less direction-dependent because the refrigerant jet inside the balloon is directed to produce the lowest ablation temperatures in a large circular zone on the anterior third of the balloon. As such, cryoballoon ablation may be expected to isolate the muscular PV sleeves, as well as the PV antrum (eFig. 15.17).

A series of technical modifications have been implemented to the second-generation cryoballoon system, which improved the simplicity, safety, and efficacy of the procedure. The new design improves cooling properties, including reengineering of the cryogen ports to ensure formation of a larger and homogeneous hemispheric cooling zone (involving the entire leading hemisphere of the balloon surface) compared to

eFig. 15.17 Voltage Map of the LA and Pulmonary Veins (PVs) (Posteroanterior View) Is Performed Before (A) and After (B) PV Isolation Using the Second-Generation Cryoballoon. Endocardial atrial bipolar electrogram with amplitudes of greater than or equal to 0.5 mV are purple, and those with amplitudes of less than 0.3 mV are shown in red, with interpolation of color for intermediate amplitudes. Note the voltage abatement at the level of the antrum of each of the PVs, indicating the level of ablation achieved using the second-generation 28-mm cryoballoon. *LIPV*, Left inferior PV; *LSPV*, left superior PV; *RIPV*, right inferior PV; *RSPV*, right superior PV.

equatorial cooling zone in the previous iteration. In addition, the new system allows insertion of a stiffened circumferential mapping catheter through the distal lumen of cryoballoon for the recording of PV potentials during ablation. Unfortunately, the long distal tip of the second-generation cryoballoon often precludes real-time recording of PV potentials. Currently under evaluation, the third-generation cryoballoon has its tip shortened by 40% to allow positioning of the circumferential mapping catheter at the PV ostium and enhance the ability to monitor real-time PV electrograms and utilize the time-to-PV isolation to guide cryoapplications.¹⁷⁹

Of note, pain reactions occur significantly less often in patients treated with cryoablation compared to RF ablation. This can allow for cryoballoon ablation procedures to be performed under conscious or deep sedation, without general anesthesia.¹⁸⁰

Disadvantages. Unlike point-by-point RF ablation, cryoenergy cannot be modified selectively in different regions around the PVs. Because uniform cooling is obtained circumferentially with the cryoballoon, structures posterior to the thinner LA wall remain susceptible to collateral damage with cooling. Furthermore, the cryoballoon is not designed for the creation of linear or focal lesions.

Also, variations in PV anatomy can influence the effectiveness of cryoballoon ablation, likely due to the difference in the venous seal obtained being dependent on the PV ostial shape and cryoballoon alignment. Also, cryoablation of the right inferior PV, in particular, remains challenging. A low anterior transseptal puncture allows more space for the balloon to be rotated posteriorly to the right inferior PV.^{167,181}

Laser Ablation

The laser ablation catheter technology (HeartLight, CardioFocus) consists of a nonsteerable, compliant balloon catheter with an adjustable diameter (maximal diameter, 35 mm) that allows treatment of PVs of 9 to 32 mm in diameter. Within the central shaft of the balloon catheter is a 2 Fr endoscope that permits real-time visualization of the target tissue. The central shaft also contains lumens for circulating deuterium dioxide (D_2O) to cool the balloon and a maneuverable optical fiber that generates a 30-degree arc/spot of both nonablative visible light and near-infrared ablative light energy (Fig. 15.41).^{182–184}

Ablation technique. The laser balloon is inserted at the PV antrum through a 16 Fr steerable transseptal sheath. Selective PV angiography or ICE can be used to verify appropriate position of the balloon (see Fig. 15.41). Varying balloon inflation pressure allows for adjustment to the individual PV anatomy to optimize PV occlusion and maximize balloon-tissue contact. The balloon is filled with a mixture of contrast and D_2O and irrigated internally at 20 mL/min to minimize absorption of laser energy. Once the balloon is deployed, the endoscope enables real-time visualization through the face of the balloon (both the tissue and blood in contact with the balloon) at the targeted PV antrum and monitoring for the intrusion of blood into the space between the balloon and the tissue.¹⁸³

The arc generator consists of an optical fiber located within the central shaft that projects a 30-degree arc of light onto regions of balloon-tissue contact guided by an endoscopic view of the PV antrum (areas of balloon-tissue contact are visualized as blanched white, whereas

contact with blood is visualized as red). This arc serves as an aiming beam for laser delivery and can be maneuvered along the balloon face with endoscopic visualization to facilitate individual lesion application in an anatomically flexible lesion design that adapts to the highly variable PV anatomy (Fig. 15.42). Once the proper location is identified, a diode laser is used to deliver laser energy at 980 nm. The laser fiber can be advanced or withdrawn to shift the site of lasing along the longitudinal axis of the catheter, and can be rotated to any location on the face of the balloon.^{184,183}

Laser energy is delivered at power output of 5.5 to 12 W for 20 to 30 seconds, depending on the thickness of tissue, proximity of the esophagus or phrenic nerve, and presence of blood in the field of view. To minimize the risk of thrombus formation, a 5.5-W energy is applied for 30 seconds when ablation is required in regions of overlapping moving blood along the periphery of the endoscopic view. Stagnant blood at the center of the endoscopic image represents blood from the target PV that is completely occluded by the balloon; ablation is avoided in this region due to a high risk of thrombus formation at any laser energy dose.¹⁸⁴

Under visual guidance, ablation lesions are deployed in a point-by-point fashion in a circumferential, contiguous, and overlapping manner around the PV. Each individual ablation lesion covers 30 degrees of a circle, and lesions are overlapped by 30% to 50% to minimize gaps between adjacent lesions (lesions can be tracked visually using special software, see Fig. 15.42). Because the catheter shaft obscures one-fifth of the circumference, the endoscope has a 115-degree field of view; thus catheter rotation is required to complete the ablation around the circumference of the PV antrum. Esophageal temperature is continuously monitored and energy delivery is terminated if the esophageal temperature exceeds 38.5°C. During ablation of the right superior PV, phrenic nerve pacing is performed from the SVC to monitor for phrenic nerve injury (using similar technique to that previously described for cryoballoon PV isolation).

Importantly, the laser balloon does not have the capability of simultaneous mapping and ablation. Mapping of PV potential is performed using a ring catheter before and after ablation. The ring catheter should not be left in the same PV while the laser balloon is deployed and during circumferential ablation because its shaft can impede balloon-tissue

Fig. 15.42 Endoscopic Visual Guidance for Laser Ablation. (A) Touchscreen snapshot of the endoscopic ablation system console. (B) An endoscopic view is shown with the balloon positioned in the left superior pulmonary vein (LSPV). At left, The maneuverable aiming and ablation spot is shown. The carina between the two left-sided veins and the left atrial appendage (LAA) can be visualized. The blind spot created by the shaft on the eccentric endoscope is highlighted by the dotted line. At right, Visualization of lesion overlapping (LightTrac software). The lesions are highlighted by dotted lines. (From Bordignon S, Chun KR, Gunawardene M, et al. Endoscopic ablation systems. *Expert Rev Med Devices*. 2013;10:177–183.)

contact. After completion of the ablation circle, the balloon is deflated, and the ring catheter is inserted into the PV to assess for electrical isolation. However, if PV isolation is incomplete after a single ablation, the ring catheter may be placed distally to the inflated laser balloon to visualize PV electric activity online during laser energy application. In this case, the shaft of the ring catheter is positioned opposite to the presumed electrical gap to avoid incomplete PV sealing at the targeted ablation site.

The laser ablation catheter technology offers distinct advantages over both RF ablation and the cryoballoon catheter. Unlike point-by-point RF ablation, the laser balloon offers stable catheter position with limited navigation efforts and without the use of an electroanatomic mapping system. Unlike the cryoballoon catheter, the visually guided laser balloon is unique in that it uses a compliant, variable diameter balloon, thus allowing a single balloon catheter to accommodate multiple PV sizes and shapes. In addition, the endoscope provides real-time direct visualization of the target tissue. Another important feature is the ability to customize the ablation lesion and selectively titrate energy to each part of the circumferential lesion set, similar to point-by-point RF ablation. With other balloon catheters, the operator cannot choose which part of the balloon would deliver ablative energy or adjust the intensity of tissue destruction around the balloon; as a result, the portion of the LA adjacent to the esophagus or phrenic nerve receives the same energy as those areas where deeper lesions are desired.¹⁸⁵

Endpoints of Ablation

Common intraprocedural endpoints of circumferential antral PV isolation include electrical isolation of all PVs, noninducibility of AF, and elimination of residual potentials inside the circumferential ablation lines. Importantly, these endpoints, even when successfully achieved during the procedure, often do not persist over time, both in patients with and in those without AF recurrences. Nevertheless, there is a consensus on the importance of the complete bidirectional electrical isolation of all PVs as a procedural endpoint. On the other hand, less agreement exists on the value of the other endpoints.¹

Electrical Disconnection of All Pulmonary Veins

The endpoint of ablation is complete bidirectional electrical isolation of all four PVs, as described earlier for segmental ostial PV isolation. According to the 2017 HRS/EHRA/ECAS/APHRS/SOLAECE expert consensus statement, achievement of electrical isolation requires, at a minimum, assessment and demonstration of entrance block into the PV. Monitoring for PV reconnection for 20 minutes following initial PV isolation is reasonable. In addition, pharmacological provocation with adenosine and demonstration of exit block may be considered.¹

When en bloc encirclement of ipsilateral PVs (with no ablation line between the PVs) is performed, assessment of PV entrance and exit block is simplified by placing the ring catheter in one PV and the ablation catheter in the ipsilateral PV, and pacing from the ablation catheter. If there are no PV potentials recorded on the ring catheter during NSR and ipsilateral PV capture occurs (indicated by appearance of PV potentials on the ring catheter) but does not conduct to the LA (that must no longer be in AF to assess), this demonstrates both entrance and exit block into and out of both PVs (eFig. 15.18).

Elimination of Residual Potentials Inside the Circumferential Ablation Lines

The value of complete voltage abatement (i.e., reduction of the atrial electrogram amplitude by greater than 80% or a decrease to less than 0.1 mV as determined by local electrogram analysis and voltage mapping) inside the circumferential ablation lines in preventing the recurrence

of AF remains controversial and requires further investigation (see eFig. 15.17). Some studies suggested that the elimination of residual potentials inside the LA-PV junctions or carina after PV isolation offer an incremental benefit on the recurrence of AF. In contrast, other studies showed no additional benefit of this approach.

Noninducibility of Atrial Fibrillation

Induction of sustained AF is thought to indicate the presence of a potential atrial substrate capable of maintaining AF; however, its value as a predictor for clinical outcome remains controversial. Elimination of PV potentials correlates with clinical success better than the acute suppression of AF inducibility. However, a successful outcome is sometimes observed without complete PV potential elimination, and some supposedly unsuccessfully treated patients experience remarkable improvement with a previously ineffective drug.

Different pacing protocols and multiple definitions of inducibility of AF have been employed in different studies. Aggressive pacing protocols can decrease the specificity, yet more conservative pacing protocols can potentially decrease the predictive value. In fact, aggressive atrial pacing (at PCLs shorter than 180 milliseconds) can induce AF in up to 26% of patients without a history of AF. Further investigation is needed to optimize the specificity of using AF induction as an endpoint for AF ablation.

Commonly, induction of AF is attempted by burst pacing at a PCL of 250 milliseconds with sequential decrement down to 200 milliseconds (as long as 1:1 capture is maintained) for 5 to 10 seconds at least three times from the CS and then repeated from the RA. If AF is not inducible, isoproterenol (10 to 20 µg/min IV infusion) is then administered, and atrial pacing is repeated. Also, AF induction by a 30-joule external biphasic shock delivered during the vulnerable period of atrial refractoriness (i.e., synchronized to the R wave) may predict recurrent AF after PV isolation. This predictor of AF recurrence can provide additive information over inducibility with burst atrial pacing alone.

Many (up to 57%) patients with paroxysmal AF have no inducible AF after PV isolation. This subset can represent a group that can potentially benefit from PV isolation alone and do not require additional substrate modification. Induction of AF should prompt reconfirmation of complete electrical isolation in all PVs. If AF remains inducible despite complete PV isolation, additional substrate-based atrial ablation may be considered (see later discussion).¹⁸⁶

Outcome

Circumferential antral PV isolation (with an endpoint of electrical isolation of all PVs) has become the most widely used AF ablation strategy, and is currently recommended during all AF ablation procedures.

Radiofrequency Pulmonary Vein Isolation

In patients with paroxysmal AF, the rates arrhythmia-free survival at 12 months following RF circumferential antral PV isolation ranges between 59% and 89%. Circumferential antral PV isolation offers a better outcome compared with ostial segmental PV isolation for paroxysmal AF (approximately 71% vs. 64%). The incremental clinical benefit of adjuvant linear LA ablation or complex fractionated atrial electrogram (CFAE) ablation, or both, in patients with paroxysmal AF has been controversial and is likely to be small or negligible. For patients with persistent AF, the success rates of circumferential antral PV isolation (approximately 50% to 70%) are less than for paroxysmal AF but are still better than those achieved by ostial segmental PV isolation, and adjunctive substrate modification seems to offer additional benefit in AF control, although this remains controversial.¹⁸⁷

eFig. 15.18 Demonstration of Entrance and Exit Block From Both Right-Sided Pulmonary Veins (PVs). The PV catheter is situated in the right superior PV (RSPV), and the ablation catheter in the right inferior PV (RIPV), after antral isolation of both right PVs as a unit. *At left*, pacing is performed from the RIPV ablation catheter, showing capture of potentials (inferred by conduction to the RSPV), but no conduction to the left atrium that remains in consistent sinus rhythm. No PV potentials are seen in either the ablation (RIPV) or RSPV catheter during the two sinus rhythm complexes at right (entrance block into both PVs). *Abl D*, Distal ablation site; *Abl P*, proximal ablation site; *CS*, coronary sinus; *HIS D*, distal His bundle; *HIS P*, proximal His bundle.

Cryoballoon Pulmonary Vein Isolation

Studies comparing cryoablation with open-irrigated RF ablation in the setting of paroxysmal AF ablation demonstrated statistical equivalence between the two technologies in terms of safety and efficacy, with arrhythmia-free survival over the first 1 to 2 years of follow-up ranging from 54% to 85%. Limited data also suggest comparable outcomes in patients with persistent AF, and comparable rate of freedom from AF at 1 year after a single RF procedure (42% to 67%).^{188–192}

Major procedure-related adverse events with the second-generation cryoballoon have been reported in approximately 5% of patients, with phrenic nerve injury being the most important complication. Phrenic nerve injury is significantly more common following second-generation cryoballoon ablation (approximately 3% to 5%) as compared to RF ablation. Nonetheless, this rate is much less than that observed with the first-generation cryoballoon system (up to 13%). Phrenic nerve palsy generally is transient, with complete resolution observed within 1 year in most cases. In a recent report, the incidence of right phrenic nerve injury during the procedure and persistent phrenic nerve injury was 9.0% and 3.0%, respectively; however, all patients recovered spontaneously during follow-up.¹⁹³ The risk for persistent phrenic nerve injury can be minimized by ensuring the cryoballoon position is as antral as possible, by using the bigger (28 mm) cryoballoon, and by close monitoring of phrenic nerve function (including CMAP monitoring) during ablation.^{188–192}

The rate of esophageal thermal lesions detected by endoscopy following ablation using the second-generation cryoballoon ranges between 3% and 19%. Compared to esophageal lesions after RF-based ablation, lesions after cryoballoon ablation tend to be more superficial, asymptomatic, and frequently heal in a few weeks. Importantly, the incidence of atrioesophageal fistula is very rare. The risk of esophageal injury can potentially be avoided by avoiding freezing durations exceeding 4 minutes, avoiding application of more than 2 freezes to a PV, and avoiding balloon nadir temperatures colder than -60°C . Also, monitoring of luminal esophageal temperature during cryoablation and using a cutoff of 12°C to 15°C for interrupting freezing can help minimize the risk of esophageal damage.

It has become evident that cryoballoon ablation can be associated with PV stenosis (the rate of symptomatic PV stenosis or PV stenosis requiring intervention was 0.17%). A distal position of the cryoballoon with respect to the PV ostium, especially when using the smaller 23-mm balloon, can potentially increase the risk of these complications. It is possible that using the big (28-mm) cryoballoon for all veins can help direct cryothermal lesions proximal to the PV ostium at the antral level and thereby reduce the risk of phrenic nerve injury and PV stenosis.

Late PV electrical reconnection occurs mostly at the superior aspects in superior PVs and at the inferior quadrants of inferior PVs, and is most common in the right inferior PV. Notably, the incidence and characteristics of PV reconnections after a second-generation cryoballoon ablation were similar between patients with and those without clinical AF recurrences.

Laser Balloon Pulmonary Vein Isolation

The laser ablation catheter technology appears to be equivalent to RF ablation with respect to efficacy and safety in patients with paroxysmal AF, with arrhythmia-free survival over the first year of follow-up ranging from 60% to 88%. In several studies, the rate of acute PV electrical isolation achieved using the laser balloon ranged from 98% to 100%, with a highly durable rate of isolation of the PVs demonstrated on remapping studies. Laser balloon ablation is associated with higher incidence of diaphragmatic paralysis as compared to RF ablation (3.5% vs. 0.6%), but lower risk of severe PV stenosis (0% vs. 2.9%). In a single-center randomized study, AF recurrence after ablation was similar

using the laser balloon compared with the first-generation cryoballoon. The initial clinical experience with this technology suggests the ability to achieve reliable and lasting PV electrical isolation in patients with highly variable PV shapes and sizes.^{183,184}

CIRCUMFERENTIAL LEFT ATRIAL ABLATION

Rationale

Attempts to replicate the results of the maze procedure in the EP laboratory have consisted of the creation of linear lesions in the LA or RA, or both. In the past, multiple catheters with coil electrodes positioned against the atrial wall were used to create the linear lesions without having to reposition the catheter repeatedly. Currently, linear ablation lesions are created with individual contiguous applications of RF energy on a point-by-point basis. RF ablation is performed circumferentially around the ipsilateral PVs, with the endpoint of ablation being the absence or marked reduction (80%) in the amplitude of electrical signals within the encircling lesions.

Whereas the efficacy of PV isolation depends on complete and lasting PV disconnection from the LA, the efficacy of circumferential LA ablation does not. This finding highlights the fact that circumferential LA ablation (also referred to as wide-area LA ablation or circumferential PV ablation) eliminates AF by mechanisms other than complete PV isolation. Several mechanisms of action can be involved. First, there is substrate modification by LA compartmentalization. Approximately 25% to 30% of the LA myocardium is excluded by the encircling lesions, thereby limiting the area available for circulating wavelets needed to perpetuate AF. The ablation lines can also eliminate anchor points for rotors or mother waves that drive AF and make reentry pathways unsuitable. Autonomic denervation by ablation of vagal inputs to the posterior LA wall is another potential mechanism. Furthermore, the ligament of Marshall, which inserts in close proximity to the left superior PV and can be a source of triggers for AF, can potentially be eliminated by the ablation line that encircles the left-sided PVs. Modification of PV arrhythmogenic activity can also be operative. By encircling the PVs, LA ablation can potentially eliminate the triggers and driving mechanisms of paroxysmal AF that arise in the PVs. Although complete conduction block across the encircling lesions may not be achieved, decremental conduction can occur, particularly at shorter CLs, and it can impede the conduction of PV tachycardias to the LA.

There are several differences between circumferential LA ablation and PV isolation strategies. From a mechanistic standpoint, segmental ostial ablation electrically isolates the PVs, thereby eliminating the arrhythmogenic activity in the PVs that triggers or perpetuates episodes of paroxysmal AF. However, sources of AF that do not originate in the PVs and the substrate that supports the maintenance of AF are not addressed by PV isolation. From a technical aspect, segmental ostial and circumferential antral PV isolation techniques require the insertion of two catheters into the LA, whereas linear LA ablation requires only a single catheter in the LA. Also, while PV isolation requires the identification of PV potentials, circumferential LA ablation is primarily an anatomic approach to ablation. Furthermore, the risk of PV stenosis, which is a major concern during ostial PV isolation, is minimized during circumferential LA ablation because most ablation sites are more than 1 cm away from PV ostia.

Electroanatomic Mapping

The ablation catheter is advanced into the LA through a transseptal puncture. A nonfluoroscopic 3-D electroanatomic navigation system is used for generating and validating the continuity of the circular ablation lines (see Fig. 6.36). Integration of CT or CMR scans into the electroanatomic mapping system improves visualization of complex

LA geometries and can potentially improve the safety and success of catheter ablation for AF.

If validation of the circumferential lesions around PVs and the completeness of conduction block across the ablation lines are to be used as endpoints for the ablation procedure, propagation maps have to be created before and after RF ablation. In addition, the collected data can be displayed as voltage maps, which can be useful to define scar areas and electrically diseased tissues. In patients in NSR at the beginning of the procedure, maps are acquired during pacing from the CS or RA at a CL of 600 milliseconds. In patients in AF at the end of the mapping procedure, electrical cardioversion to restore NSR is performed to allow stimulation maneuvers.

Target of Ablation

The ablation lines are typically created with encircling lesions around the left- and right-sided PVs, 1 to 2 cm from the PV ostia. The circumferential ablation lines may surround each of the PVs, or, instead of encircling each PV, one big circle is placed around the PVs of each side. An ablation line is also created across the LA roof to connect the two circumferential ablation lines and often another ablation line across the mitral isthmus between the inferior portion of the left-sided encircling lesion and the lateral mitral annulus (see later discussion) (Fig. 15.43). In some patients, additional ablation lines are created in the septum and anterior wall that extend from the roof line to the mitral isthmus. At present, the number and location of LA linear lesions should be tailored to the individual patient. The ideal configuration would combine technical ease and safety with long-term control of AF.

Ablation Technique

Once an electroanatomic map of the main PVs and LA has been adequately reconstructed, RF ablation is performed 1 to 2 cm from the PV

ostia to encircle the left- and right-sided PVs. However, because there is a narrow rim of atrial tissue between the anterior aspect of the left superior PV and the LAA in approximately 50% of patients, ablation within 1 cm of the ostium of this vein sometimes is required.

Circumferential ablation lines are usually created starting at the lateral mitral isthmus and withdrawing the ablation catheter tip posteriorly and then anteriorly to the left-sided PVs, passing between the left superior PV and the LAA before completing the circumferential line on the posterior wall of the LA. The ridge between the left superior PV and the LAA can be identified by fragmented electrograms caused by collision of activity from the LAA and left superior PV-LA. The LAA is identifiable by a significantly higher impedance (more than 4 Ω higher than the LA mean), a high-voltage local bipolar electrogram, with characteristically organized activity in fibrillating patients. The right PVs are ablated in a similar fashion. Ablation sites are tagged on the model of the LA created with the electroanatomic mapping system, and that system is used for generating and validating the continuity of circular lines.

An irrigated-tip ablation catheter is typically used with power settings of 20 to 30 W on the posterior wall, 35 to 50 W elsewhere, with a temperature limit of less than 43°C. Alternatively, a solid 8-mm-tip ablation catheter may be used, with RF energy set to a target temperature of 55°C to 65°C and a power limit of 70 to 100 W. The power and temperature limits are reduced in the posterior LA wall to 50 W and 55°C to minimize the risk of injury to the surrounding structures. A series of RF applications is delivered until the maximum local bipolar electrogram amplitude decreases by 80% to 90% or to less than 0.05 to 0.1 mV, or to a maximum RF duration of 40 milliseconds, whichever comes first. Alternatively, RF energy is applied continuously on the planned circumferential ablation lines as the catheter is gradually dragged along the line, with repositioning of the catheter tip every 10 to 20

Fig. 15.43 Circumferential Left Atrial Ablation. Segmented three-dimensional computed tomography scan of the left atrium (LA) and pulmonary veins (PVs) shown in posteroanterior (A), modified posteroanterior (B), right anterior oblique (C), and left lateral (D) views. Contiguous radiofrequency lesions (red dots) are deployed in the LA, creating circumferential lines around ipsilateral PVs. An ablation line is also created across the LA roof to connect the two circumferential ablation lines and another ablation line across the lateral mitral isthmus between the inferior portion of the left-sided encircling lesion and the lateral mitral annulus. LAA, LA appendage; LIPV, left inferior PV; LSPV, left superior PV; MA, mitral annulus; RIPV, right inferior PV; RSPV, right superior PV.

seconds. Continuous catheter movement, often in a to-and-fro fashion over a point, helps keep the catheter tip temperature down as a result of passive cooling.

Power, impedance, and electrical activity are monitored continuously during navigation and ablation. Impedance can increase suddenly if a thrombus forms on the catheter tip. A much more useful indicator is a 40% to 50% reduction in the power delivered to reach target temperature. If thrombus formation is suspected, catheter withdrawal from the LA without advancing the transeptal sheath can be necessary to avoid stripping any thrombus present on the catheter tip as the catheter is withdrawn into the sheath, which can result in systemic embolization.

RF application should be immediately terminated when the catheter position deviates significantly from the planned line or falls into a PV, when impedance rises suddenly, or when the patient develops cough, burning pain, or severe bradycardia.

After completion of the circular lesions around the left- and the right-sided PVs, the area within the ablation lines is explored with the ablation catheter. RF energy is applied at sites that have a local electrogram amplitude greater than 0.1 mV. In addition, when AF is still present, sites inside the encircling ablation lines where the CL is shorter than the atrial CL in the CS also are ablated.

Endpoints of Ablation

To date, circumferential LA ablation for AF has stood apart from most other types of ablation procedures in that a clear-cut EP endpoint has not been defined. The only endpoint of ablation used in most studies has been voltage abatement. Although one study suggested that complete block across the ablation lines is a useful EP endpoint, this was not confirmed in two other studies.

Voltage Mapping

The primary endpoint for circumferential ablation is the reduction in voltage within the isolated regions by more than 80% to 90% or the recording of low (less than 0.05 to 0.1 mV) peak-to-peak bipolar potentials inside the lesion, as determined by local electrogram analysis and voltage mapping.

Postablation voltage mapping is performed using the preablation map for the acquisition of new points (on the existing LA geometry) to permit accurate comparison of preablation and postablation bipolar voltage maps. After completion of the circular lesions around the left- and right-sided PVs, the area within the ablation lines is explored with the ablation catheter, and RF energy is applied at sites that have a local electrogram amplitude greater than 0.1 mV. As an anatomy-based ablation strategy, this can be the only required endpoint.

Activation Mapping

Another endpoint used for lesion validation requires the acquisition of two activation-propagation maps during CS and RA pacing for left- and right-sided PVs, respectively. The rationale behind this setting is to pace from a site close to the lesions and shorten conduction time to the ablation site, thereby allowing detection of delayed activation inside the circular line.

Several criteria are used to define line continuity: (1) low peak-to-peak bipolar potentials (less than 0.1 mV) inside the lesion, as determined by local electrogram analysis and voltage mapping; (2) local activation time delay of more than 30 milliseconds between contiguous points lying in the same axial plane on the external and internal sides of the line, as assessed by activation mapping; and (3) gaps in the ablation lines, defined as breakthroughs in an ablated area and identified by sites with single potentials and by early local activation. Changes in activation spread are also evaluated with propagation mapping. Incomplete block

is revealed by impulse propagation across the line; in this case, further RF applications are given to complete the line of block.

Importantly, the only predictive criterion for a successful ablation seems to be the amount of postablation low-voltage encircled area. Therefore validation of the circumferential lesions around PVs by pacing maneuvers, the completeness of conduction block across the ablation lines, and the search for gaps in the ablation lines are not routinely performed.

Pulmonary Vein Isolation

Controversial data have been published regarding the influence of PV disconnection during circumferential LA ablation. Several reports suggested that complete electrical isolation of the PVs is not necessary for a successful outcome. Hence, complete PV isolation is not required as an endpoint for circumferential LA ablation. In fact, this ablation strategy typically is associated with incomplete PV isolation. Nonetheless, although PV potentials were still present in one or more PVs in 80% of patients, there usually is a conduction delay between the LA and PVs, and the prevalence of PV tachycardias is markedly reduced after circumferential LA ablation.

Of interest, conduction gaps in the ablation lines and LA-PV connection sites can be characterized by multicomponent electrograms without isoelectric lines during sinus rhythm and by multicomponent electrograms or continuous activity during AF. In one report, targeting those sites with ablation was shown to increase the PV disconnection rate during circumferential LA ablation to more than 85% of PVs, which can potentially improve clinical outcome.

Termination of Persistent Atrial Fibrillation

Termination of AF during the procedure occurs in approximately one-third of patients (more commonly in paroxysmal than persistent AF). If AF does not terminate during RF, transthoracic cardioversion is performed at the conclusion of ablation. If AF recurs immediately after the cardioversion, the completeness of the lines is reassessed, and additional ablation lines should be considered. Additional ablation consists of ablation lines created along the LA septum, roof, posterior mitral isthmus, or anterior wall, on the basis of the presence of fractionated or rapid atrial activity (see later discussion).

Organized Atrial Arrhythmias

When LA ablation is performed during an ongoing episode of AF, the AF converts to NSR or to a more organized type of atrial tachyarrhythmia in approximately 20% to 30% of patients. LA ablation can create macroreentrant circuits, thus mediating conversion of AF into AT. The most common type of macroreentry is mitral isthmus-dependent macroreentry. In addition, macroreentrant circuits (single or multiple-loop reentry as well as small-loop reentry) can be created by gaps in the ablation lines that encircle the PVs, mostly located on the ridge between the LAA and the left superior PV. Entrainment and activation mapping should be performed during organized ATs, and detailed online mapping to search for gaps in the ablation lines should be performed. RF applications at the gaps in the circumferential ablation lines or linear ablation across the lateral mitral isthmus or LA roof can be required for elimination of those ATs.

Noninducibility of Atrial Fibrillation

Whether noninducibility of AF can be used as a clinical endpoint of ablation in patients with AF who have undergone circumferential LA ablation is still controversial. Some reports found that inducibility of AF after ablation was an independent predictor of recurrent AF. One study suggested performing additional ablation when AF is still inducible after the initial procedure. Circumferential LA ablation renders AF

noninducible by rapid atrial pacing in approximately 40% of patients with paroxysmal AF. With additional LA ablation lines, the percentage of patients in whom AF was rendered noninducible increases to approximately 90%, and such an endpoint is associated with a better clinical efficacy than when AF was still inducible. Conversely, other reports showed a rather low predictive accuracy of the postablation stimulation test that prohibited its use as a reliable procedural endpoint for individual patients; these reports suggested that continuation of ablation caused by a positive stimulation test or AF persistence may lead to overtreatment in a substantial proportion of patients.

Outcome

In multiple reports, long-term success was achieved in approximately 74% of patients with paroxysmal AF and in 49% of patients with persistent or permanent AF.

One study suggested that circumferential LA ablation to encircle the PVs is preferable to segmental ostial PV isolation as the first approach in patients with symptomatic paroxysmal AF. In contrast, another prospective randomized study comparing the two strategies showed the opposite results. Not unexpectedly, the opposite results in the two studies were obtained because of the large variability in the success rate observed in patients undergoing circumferential LA ablation (88% vs. 47%), whereas the success rates in patients undergoing segmental ostial PV isolation were similar (67% vs. 71%).

Although some studies reported that PV electrical isolation was not related to the success of the procedure, more recent studies found that rigorously achieving complete PV electrical isolation improved the success of circumferential LA ablation as compared with the purely anatomic endpoint of abatement of electrical activity by the ablation catheter recording within the encircled regions. Currently, the Heart Rhythm Society's consensus statement on AF ablation strongly urges demonstration of PV isolation with whatever ablation strategy used. Because PV isolation is not necessarily achieved (or even intended) with circumferential LA ablation, this procedure has not been commonly used.

LINEAR ATRIAL ABLATION

Linear ablation lesions in the LA and RA in conjunction with circumferential LA ablation or circumferential antral PV isolation were proposed to improve the clinical outcome of AF ablation by modifying the atrial substrate that maintains AF. Ablation strategies can involve the LA roof line connecting the left and right superior PVs, lateral mitral isthmus line connecting the mitral annulus to the left inferior PV, electrical isolation of the entire posterior LA wall, and ablation of the CTI in the RA.

Left Atrial Roof Line

Rationale

Although the exact mechanism by which the LA roof supports the fibrillatory process is unclear, evidence has implicated this region in the substrate for AF. In addition, the LA roof represents a region demonstrating highly fragmented electrograms, perhaps indicating the presence of substrate capable of sustaining localized reentry or focal activity that may maintain fibrillation, and it also has the potential for supporting macroreentry around the PVs using the LA roof.

Some reports suggested that ablation at the LA roof has a direct effect on the fibrillation process, by prolonging the fibrillatory CL and terminating the arrhythmia in some patients and rendering AF noninducible in patients with inducible or sustained arrhythmia after PV isolation. This finding implicated the LA roof in the substrate maintaining AF after PV isolation.

Linear ablation was previously performed posteriorly or anteriorly across the LA. However, a posterior ablation line between the two superior PVs carries a higher risk of atriopharyngeal fistula. Transection of the anterior LA results in significantly delayed activation of the lateral LA during NSR, which has potentially deleterious hemodynamic consequences. Therefore these lines are currently substituted with the LA roof line (see Fig. 6.36).

Ablation Technique

LA roof ablation is performed after circumferential LA ablation or circumferential antral PV isolation. Commencing at the encircling lesion at the left superior PV, the sheath and catheter assembly are rotated clockwise posteriorly and are dragged toward the right superior PV. To achieve stability along the cranial LA roof, the catheter may be directed toward the left superior PV and the sheath rotated to face the right PVs, or vice versa. Two alternative methods can also be used to reach the LA roof for ablation. First, the catheter can be looped around the lateral, inferior, septal, and then cranial walls, then lay the catheter down along the cranial wall of the LA to allow dragging of the catheter by withdrawal from the left to the right superior PV ostia. Second, the catheter can be maximally deflected to form a tight loop near the left superior PV, with the tip facing the right PVs. Releasing the curve positions the catheter tip adjacent to the right superior PV ostia and allows dragging back to the left PV. Using a catheter with bidirectional deflection capability, or a unidirectional catheter in a deflectable sheath, can facilitate ablation on the LA roof.

The stability of the catheter is monitored during RF applications with the use of the proximal electrograms, intermittent fluoroscopy, or a navigation system to recognize inadvertent displacement of the catheter. Electroanatomic mapping is used for real-time monitoring and to tag the ablation sequence. RF energy is delivered for 60 to 120 seconds at each point while the local atrial electrograms are monitored. Local potential elimination or formation of double potentials during pacing or AF signifies the effectiveness of ablation locally.

Endpoints of Ablation

The EP endpoint of ablation is the demonstration of a complete line of block joining the two superior PVs. Following the restoration of NSR, complete linear block is defined by point-by-point mapping of an online corridor of double potentials along the entire length of the LA roof during pacing from the anterior LA (from the LAA or the distal CS) or during NSR and by demonstration of an activation detour circumventing the right and left PVs to activate the posterior wall caudocranially (instead of the craniocaudal activation typically observed during NSR and LAA pacing), with no conduction through the LA roof. When residual conduction is demonstrated, detailed mapping is performed to identify and ablate gaps in the linear lesion.¹

Outcome

Previous studies have shown that the addition of linear ablation to PV isolation has improved outcomes. On the contrary, more recent randomized studies and meta-analyses found no incremental benefit of additional LA linear ablation over PV isolation alone in both persistent and paroxysmal AF.¹⁹⁴

A successful linear ablation strategy depends on achieving durable complete conduction block across the ablation lines. However, although acute success rates are high, reconduction rates via gaps in the ablation line late after the procedure remain high, likely explaining the lack of benefit associated with additional linear ablation. Importantly, conduction gaps in the ablation lines may not only result in recurrence of AF, but may also be proarrhythmic, promoting the development of gap-related macro- or microreentrant ATs. Further, the efficacy of linear

ablation in modifying the substrate that maintains AF has been questioned, since several studies showed that the addition of linear ablation lesions did not reduce the rate of recurrent AF.^{30,146,194–196}

Of note, the sinus node artery courses over the LA roof from its source in the circumflex coronary artery to the sinus node region, and can be injured or destroyed with a roof line, resulting in SND.

Left Atrial Posterior Wall Isolation

Rationale

The role of the LA posterior wall in initiation and perpetuation of AF has been suggested by both human and animal studies. The LA posterior wall embryologically originates from the same cells of the primordial PV, suggesting that both of these structures potentially contribute to the development of AF. Focal discharges initiating AF not infrequently originate from the posterior LA. Furthermore, the LA posterior wall can harbor rotors that can participate in maintaining AF. Therefore targeting the LA posterior wall ablation can potentially modify the substrate responsible for both initiation and maintenance of AF. Several studies have suggested that deployment of linear lesions along the LA to exclude the posterior wall in addition to PV ablation can potentially improve long-term outcome, at least in cases with nonparoxysmal AF.^{197,198}

Ablation Technique

Following circumferential PV ablation, isolation of the LA posterior wall is achieved by an ablation line joining the two superior PVs (LA roof line) and a second ablation line joining the two inferior PVs (LA floor line). The lateral boundaries of the box isolation are formed by the contiguous lesions previously created by circumferential PV ablation, forming the so-called “box lesion” (Fig. 15.44).¹⁹⁹

Ablation of the LA roof is performed as described earlier. Following the roof line, a contiguous line of ablation lesions joins the inferior PVs to isolate the LA posterior wall. Commencing at the lesion at the left inferior PV, the sheath and catheter are rotated clockwise posteriorly and dragged toward the right inferior PV. RF power output is limited to 20 to 30 W to minimize the risk of atrioesophageal fistula.

During ablation, the slowing of LA posterior wall activity with progressive completion of the posterior LA rectangle and termination of AF can be observed in some patients. Complete linear block can be verified by the demonstration of no conduction through the LA roof and inferior lines by point-by-point sequential mapping either conventionally or by electroanatomic mapping (eFig. 15.19), or by recording and pacing from a catheter on the posterior wall showing lack of conduction from LA to these electrodes and capture of potentials without conduction to LA in a manner analogous to showing entrance and exit block after PV isolation. Persistent conduction across to the posterior wall should prompt meticulous online mapping to identify and ablate gaps in the linear lesions.

Importantly, the path of the esophagus is invariably crossed perpendicularly while creating the floor line of the box lesion, which can hinder the ability to create a complete line of block.¹⁹⁹

An alternative strategy is to target the entire LA posterior wall by extensive nonlinear ablation lesions until complete isolation is achieved (Fig. 15.45). Also, some investigators suggested a more individualized approach guided by scar (voltage) mapping. The latter approach employs ablation of the LA posterior wall only in patients with low voltage areas in that region, with scar homogenization as the goal of the ablation.²⁰⁰

Endpoints of Ablation

The endpoints of box isolation are the demonstration of the absence or dissociation of electrical activity within the ablated zone (i.e., entrance block), as well as failure to capture the LA outside the isolated region

(i.e., exit block) during pacing from the posterior LA and all PVs (after the restoration of NSR) (Fig. 15.46).^{197,199}

Outcome

Studies the value of LA posterior wall isolation as an adjunctive strategy in combination with circumferential PV isolation have arrived at conflicting results. In a study in patients with paroxysmal AF, exclusion of the LA posterior wall did not improve the outcome of circumferential PV isolation for AF. On the other hand, a recent meta-analysis demonstrated that PV isolation with posterior wall isolation provided additional benefits over PV isolation alone, with a significant reduction in AF recurrence, but no significant difference in AT recurrence.^{197,201}

Lateral Mitral Isthmus Line

Rationale

Emerging evidence has implicated regions of conduction slowing and block associated with atrial remodeling in the substrate predisposing to AF. In the LA, studies demonstrated preferential propagation that is closely correlated with muscle fiber orientation along the posterior LA and circumferentially around the mitral annulus. Such preferential propagation occurring in response to functional or anatomic conduction block (perhaps exacerbated by AF or conditions predisposing to AF) is capable of facilitating reentry using the mitral isthmus, as recognized with common forms of LA macroreentry, and thus can have a role in the milieu that maintains AF.

Because of the contiguity with the left PVs and LAA, ablation of the mitral isthmus results in a long (functional) line of conduction block that transects the lateral LA from the mitral isthmus to the roof. Its EP consequences can be considered analogous to those produced by CTI ablation, in which a short line is amplified by the crista terminalis to result in a long line of functional conduction block. It is thus possible that ablation of the mitral isthmus, as an adjunct to other ablation strategies for AF, helps modify a large region of the LA substrate for AF by eliminating anatomic or functional reentry involving the mitral isthmus or PVs. In addition, it can eliminate arrhythmogenic triggers arising from the ligament of Marshall.

LA macroreentrant ATs can develop following catheter ablation of AF in up to 50% of cases. The most common type of LA macroreentry is mitral isthmus-dependent AT, and it seems more likely that this type of AT is a direct result of LA ablation. The potential of this complication underscores the importance of an ablation line across the mitral isthmus. Ablation of the mitral isthmus is discussed in detail in Chapter 13.

Outcome

Most studies have failed in demonstrating an incremental benefit of ablation of the lateral mitral isthmus over PV isolation alone, even when combined to linear ablation across the LA roof. It is important to recognize that continuous linear lesions are difficult to achieve, even under direct visualization during intraoperative ablation. It has been shown that creating transmural permanent lines of block across the mitral isthmus line in particular is technically challenging and sometimes requires ablation deep within the CS.

Gaps within the ablation lines, whether secondary to areas of recovery or areas missed initially, can produce areas of slow conduction and a substrate for macroreentry. Therefore when linear LA ablation is applied, complete bidirectional conduction block across the ablation lines should be verified to reduce the risk of development of macroreentrant ATs related to gaps in the ablation lines (refer to Chapter 13 for detailed discussion). Bidirectional block at the lateral mitral isthmus can be acutely achieved in 65% to 92% of patients, with ablation within CS being required in about two-thirds of patients.²⁰²

eFig. 15.19 Confirmation of Block Across the Ablation Line. Posterior views of three-dimensional electroanatomic (Rhythmia) activation map of the left atrium (LA). Circumferential radiofrequency (RF) ablation is performed around ipsilateral pulmonary veins (PVs), and an ablation line (*white dots*) is performed connecting the inferior PVs. (A) The activation color map obtained during atrial pacing (*asterisk*) just inferior to the ablation line shows incomplete line of block, with wavefront propagation through a gap in the medial aspect of the ablation line (*arrow*). (B) Additional RF applications (*purple dots*) were delivered at the region of gaps in the ablation line. Then, activation mapping during pacing from the same atrial site was repeated; note the formation of an early-meets-late zone (*violet to red*) along the entire length of the ablation line demonstrating the achievement of a continuous conduction block. *LIPV*, Left inferior PV; *LSPV*, left superior PV; *RIPV*, right inferior PV; *RSPV*, right superior PV.

Fig. 15.44 Left Atrial Posterior Wall Isolation (Box Lesion). Three-dimensional reconstruction of the left atrium (LA, posterior view) using the Rhythmia electroanatomic system before (A) and after (B and C) catheter ablation of atrial fibrillation. Small white circles are tagged sites at which RF energy was applied to isolate the pulmonary veins (PVs). Electrical isolation of the LA posterior wall (box isolation) is performed by an ablation line joining the two superior PVs (*roofline*) and a second ablation line joining the two inferior PVs (*inferior line*). Sites with voltage lower than 0.1 mV are red on the map, and those with voltage higher than 0.5 mV are purple, with interpolation of color for intermediate amplitudes. The gray area denotes no detectable signal (scar). Note the voltage abatement encompassing all PVs and the whole LA posterior wall within the box lesion. LAA, LA appendage; LCPV, left common PV; RIPV, right inferior PV; RSPV, right superior PV.

Fig. 15.45 Left Atrial Posterior Wall Isolation. Three-dimensional reconstruction of the left atrium (LA, posterior view) using the CARTO electroanatomic system before (A) and after (B) catheter ablation of atrial fibrillation. Small white and red circles are tagged sites at which RF energy was applied. After circumferential antral isolation of the pulmonary veins (PVs), nonlinear ablation lesions are applied to the LA posterior wall. Note the voltage abatement encompassing all PVs and the whole LA posterior wall within the box lesion. Sites with voltage lower than 0.05 mV are red on the map, and those with voltage higher than 0.5 mV are purple, with interpolation of color for intermediate amplitudes. *LIPV*, Left inferior PV; *LSPV*, left superior PV; *RIPV*, right inferior PV; *RSPV*, right superior PV.

Fig. 15.46 Left Atrial (LA) Posterior Wall Isolation. At left, intracardiac recordings from a multipolar catheter (Penta) on the LA posterior wall after ablation encompassing the area with radiofrequency applications (see figure at right; the patient had previous pulmonary vein [PV] isolation). Stimulation (S) is performed from the ablation catheter, also on the posterior wall; stimuli are followed by electrograms on Penta recordings (red arrows), while the atrium (surface electrocardiogram, coronary sinus [CS] recordings) remains in sinus rhythm. After cessation of pacing, there are no electrograms from the Penta electrodes, indicating entrance and exit block into and out of the posterior wall. *Abl D*, Distal ablation site; *Abl P*, proximal ablation site; *His D*, distal His bundle; *His M*, middle His bundle; *His P*, proximal His bundle; *LIPV*, left inferior PV; *LSPV*, left superior PV; *PA*, pulmonary artery; *RIPV*, right inferior PV; *RSPV*, right superior PV.

Due to the prospect of facilitating macroreentry with incomplete ablation as well as risk of injury to the circumflex coronary artery, routine mitral isthmus ablation (in the absence of documented perimitral macroreentry) is not currently recommended.

Cavotricuspid Isthmus Line

AF and AFL frequently coexist in the same patient. Clinical AFL occurs in more than one-third of patients with AF. AF often precedes the onset of AFL and can also develop after the successful catheter ablation of AFL. Typical AFL, usually induced either by atrial pacing or by

AF, can be observed in approximately half of patients undergoing PV isolation for AF.

Although typical AFL and AF frequently coexist, their precise interrelationship is unclear. It is possible that the same premature depolarizations that trigger AF also trigger AFL, or that the EP and structural remodeling that accompany AF also promote the occurrence of AFL, or vice versa. Evidence suggests that AF plays an important role in the genesis of typical AFL; spontaneous or induced typical AFL does not start immediately after a premature beat or burst rapid atrial pacing; rather, its onset is generally preceded by a transitional rhythm (AF) of

variable duration. AF can promote the formation of an intercaval functional line of block in the RA, which can be critical for the initiation of AFL. Also, class IC and IA antiarrhythmic drugs and amiodarone used to suppress AF commonly promote AFL.

On the other hand, it is also possible that at least some episodes of AFL can degenerate into AF. AFL with a short CL can result in fibrillatory conduction. In addition, AFL can induce atrial electrical remodeling that predisposes to development of AF.

In patients with AF and no known history of AFL, the potential benefit of adjunctive CTI ablation on the risk of recurrence of AF after PV isolation has not been confirmed by large studies. Therefore routinely performing typical AFL ablation in all patients undergoing AF ablation may not provide added clinical benefit but can potentially add time, cost, and risk.²⁰³

On the other hand, CTI ablation is recommended in patients undergoing AF ablation whenever typical AFL is observed clinically. In addition, the occurrence of typical AFL in the course of a catheter ablation procedure aimed at elimination of AF was shown to be predictive of symptomatic AFL during follow-up after PV isolation, even in patients who had no prior clinical history of AFL, a risk that was lowered by combining AF and AFL ablation in those patients. Thus supplementary CTI ablation in conjunction with AF ablation is recommended in these patients.²⁰⁴

Of note, in patients with paroxysmal AF who had periods of typical AFL, PV isolation alone, although not interrupting the reentrant circuit in typical AFL, can potentially control both arrhythmias, a finding suggesting that AF initiated by PV triggers can be the precursor rather than the consequence of AFL. This is consistent with the observation that AFL commonly starts after a transitional rhythm of variable duration, usually AF. However, these findings were not confirmed by other studies that showed no benefit of PV isolation on the risk of recurrence of typical AFL.

FOCAL IMPULSE AND ROTOR MAPPING

Rationale

FIRM is a novel mapping system (RhythmView, Abbott, Chicago, IL, United States) that uses a 64-electrode basket catheter for panoramic simultaneous recording of atrial activation and computational spatiotemporal mapping of AF.

FIRM mapping has been used to identify patient-specific AF drivers, that is, regions in the atrium that can potentially be responsible for maintaining AF, to design tailored ablation strategies. FIRM mapping records AF unipolar electrograms in a wide field-of-view across the majority of both atria and then employs physiologically directed computational methods to create activation trails, which can identify putative regions of recurrent organized rotational activity (rotors) and focal sources (focal drivers) within the atria, which appear to have a mechanistic role in sustaining AF.^{205,206}

Focal Impulse and Rotor Modulation Mapping

Initially, atrial geometry is constructed using an electroanatomic mapping system (EnSite NavX or CARTO). Typically, PV isolation is performed first; if AF persists thereafter, rotor/focal source mapping is then performed.

The technique involves use of a multipolar basket catheter (Constellation, Boston Scientific; or FIRMap, Abbott) with 8 splines, each having 8 equally spaced electrodes (total, 64 electrodes). The basket catheter is introduced via an 8.5-Fr long sheath from the femoral vein sequentially into the RA and then (transseptally) into the LA. The basket size, either 48 or 60 mm (Constellation) or 50, 60, or 70 mm (FIRMap), is selected on the basis of atrial size determined from preprocedure CT

angiography or intraprocedural ICE. Generally, the RA is mapped first and the LA second. The basket catheter is manipulated to achieve good contact with as much of the atrium as possible on the basis of fluoroscopic and ICE imaging and unipolar and bipolar electrogram quality (Fig. 15.47). Upsizing the basket catheter needs to be considered when optimal endocardial coverage (greater than 75% of atrial chamber surface) by basket catheter electrodes cannot be achieved. Downsizing the basket size should be considered when excessive basket distortion or insufficient basket expansion occurs. IV heparin is infused to achieve an ACT of more than 300 seconds.^{198,207}

Wide-area contact mapping uses monophasic action potentials to separate potentially reproducible elements (principal components) of activation in AF from bystander disorganized activation in a clinically meaningful fashion. FIRM mapping is performed during spontaneous or induced sustained AF. Unipolar atrial electrograms from the basket catheter are filtered at 0.05 to 500 Hz and recorded at 1-kHz sampling frequency (eFig. 15.20). Unipolar electrograms are recorded during AF for 1 minute and exported to a dedicated proprietary mapping system (RhythmView). Multiple 1-minute recordings are typically analyzed over a period of 5 to 10 minutes. The system filters out QRS complexes and T waves and analyzes the unipolar atrial electrograms, taking into account rate-dependent refractoriness ("restitution") and conduction slowing to determine physiologically plausible activation paths. Using phase-based algorithms, RhythmView software provides maps of putative propagation of electric activity during AF (isopotential movies and isochronal activation maps) projected onto a 2-D grid representing the endocardial surface of the atrium studied. AF (FIRM) maps are analyzed intraprocedurally to guide ablation.^{198,205,208}

Rotors are defined as phase singularities with emanating spiral waves that disorganize in surrounding tissue. Repetitive focal drivers are defined as activation emanating centrifugally from a source region. Clinically, rotors or focal drivers observed in FIRM maps are diagnosed as AF sources only if they lie in spatially reproducible regions (i.e., showing spatial stability) for minutes (i.e., showing temporal stability). This definition excludes transient or migratory activity that would be difficult to target for ablation.^{21,209}

Target of Ablation

RF ablation targets electrical rotors and focal impulses that lie in reproducible regions, with precession, on repeated analysis for thousands of cycles. Sources often cluster around the PV antra, the base of the LA and RA appendages, the LA roof, and the lateral mitral isthmus. However, sources have been found in almost all locations but are not typically within 1 cm of a valve annulus (possibly similar to the property of experimental rotors that extinguish when a nonconducting barrier is encountered).^{198,205,208,210}

Ablation Technique

Based on basket grid coordinates, referenced to electrode positions on electroanatomic shells, the ablation catheter is manipulated within the area corresponding to the center of rotation (for rotors) or focal impulse origin, as indicated by the FIRM map. Generally, the splines and electrodes at this source and surrounding region of about 2 cm² are identified and targeted by ablation (Fig. 15.48). RF ablation is performed using an irrigated-tip ablation catheter (power output, 25 to 35 W; maximum temperature, 42°C). Energy is applied with the aim of eliminating or drastically reducing amplitude of electrograms in the area (20 to 40 seconds per lesion). A lesion set is created, targeting the region within a radius of 1 to 2 cm of the rotor coordinate, until AF terminates, organizes to another tachycardia, or the entire rotor region has been ablated (which usually requires about 5 to 10 minutes of RF energy application) (see Fig. 15.48). Usual care is taken

eFig. 15.20 Basket Catheter Electrograms for Rotor Mapping. Unipolar atrial fibrillation (AF) recordings from basket catheter (*BSK*) in left atrium; 12 electrocardiogram leads (*top*) and red signals (*center*, from coronary sinus [*CS*]) show clear AF. Recordings from each basket spline are grouped by color (8 recordings from each of 8 splines). *Abl D*, Distal ablation site; *Abl P*, proximal ablation site.

to avoid damage to nearby structures such as phrenic nerve, esophagus, and AVN.

Once a lesion set is completed in a target zone, a repeat FIRM map is created. If the rotor is still present, additional RF is delivered and the map recreated. If the target rotor or source is no longer evident, other rotors or focal sources are sought. If no further sources are evident on remapping, the basket position in the atrium can be adjusted to cover additional areas not well seen before. When AF terminates during ablation, reinduction is attempted with pacing; if sustained AF is reinduced, and a new FIRM map is created.

Once no further sources can be identified, the other atrial chamber is mapped, targeted, and ablated in an identical manner. Iterative cycles of mapping of sources, ablation, remapping, and catheter repositioning

are repeated until there are no further sources (at which time cardioversion is performed) or AF cannot be reinitiated (if it has previously terminated with ablation). Basket catheters currently are available in 50-, 60-, and 70-mm diameter to accommodate most atria. In the majority of cases, baskets chosen to fit the LA work well in the RA.^{198,205,208}

Usually, an average of 3 to 5 sources is found and targeted for ablation; 80% to 90% are rotors. More are found in LA than RA, in persistent than paroxysmal AF. Mapping and ablation of rotors and focal sources adds approximately 1 hour to the procedure.

Endpoints of Ablation

RF ablation is performed to achieve local potential abatement at the ablation target area with the acute endpoint of AF source (rotor or

Fig. 15.48 Focal Impulse and Rotor Modulation (FIRM). A left atrial (LA) rotor is identified by FIRM mapping in a patient with persistent atrial fibrillation (AF) for more than 8 months. (A) AF at baseline. (B) After 1.3 min of ablation at rotor site, AF organizes to an atypical flutter. (C) After 3.1 min of ablation, the rhythm terminates to sinus rhythm. (D) Anteroseptal LA rotor on mapping diagram. (E) Anterior view of electroanatomic shells (right atrium—green, LA—gray); successful septal LA rotor ablation site (red dots; total ablated area approximately 20 cm²). *Abl D*, Distal ablation site; *Abl P*, proximal ablation site; *CS*, coronary sinus; *His D*, distal His bundle; *His M*, middle His bundle; *His P*, proximal His bundle; *IVC*, inferior vena cava; *LIPV*, left inferior PV; *LSPV*, left superior PV; *SVC*, superior vena cava.

focal impulse) elimination, as confirmed with FIRM remapping. FIRM mapping is repeated until all AF sources in both atria are identified and ablated, AF organizes into focal or macroreentrant AT, or converts to NSR.^{198,205,208}

When AF organizes into a regular AT, this is mapped and ablated with conventional approaches. Electrical cardioversion is performed if AF persists after elimination of all FIRM-identified sources and no new sources are identified on FIRM remapping.²¹¹

Outcome

Initial studies using FIRM showed that rotors and focal sources are present in the vast majority of patients with AF. Ablation of AF drivers as guided by FIRM, in the form of small numbers of stable rotors or focal sources distributed in both atria and frequently located outside the PV ostia, resulted in high rates of acute termination and long-term freedom from recurrent AF. Those studies reported superiority of FIRM in AF suppression as compared with conventional ablation techniques.

In particular, termination of persistent AT when ablating at areas indicated by mapping provided a strong validation for the technique.²⁰⁶

However, subsequent relatively small studies failed to replicate the findings of initial reports. Some of the most recent studies reported a low acute procedural success in paroxysmal and nonparoxysmal AF population after targeting the FIRM-identified rotors and very high long-term arrhythmia recurrence as compared to conventional approaches to AF ablation. Therefore an ablation strategy targeting FIRM-identified rotors, alone or in conjunction with PV isolation, remains controversial, given the lack of randomized data supporting its efficacy. Such studies are underway.^{198,210–212}

Several factors have been proposed to explain the disparate results of FIRM-guided ablation. One possible explanation is that the fundamental premise that rotors are the driving mechanism of AF may not be accurate. FIRM is based on the premise that AF is sustained by spiral waves or rotors or focal sources, or both, which were sufficiently stable in space to be eliminated by targeted ablation. It is still controversial

whether stable rotors exist in human AF and whether they are responsible for maintenance of AF, rather than a passive epiphenomenon of disorganized fibrillatory activation. The ability to determine the true mechanism of apparently focal activation can be limited by inadequate spatiotemporal resolution, insufficient sampling duration, low fidelity of interpolation, and poor differentiation of true local activation from far-field contamination. In fact, studies showed that FIRM-identified rotor sites did not exhibit quantitative atrial electrogram characteristics expected from rotors (i.e., greater electrical periodicity, unique spectral characteristics, such as higher dominant frequency and higher Shannon entropy) and did not differ quantitatively from surrounding tissue.²⁰⁹ Furthermore, one report demonstrated the lack of relationship between sites of FIRM-identified rotors and low voltage areas identified on atrial substrate maps.²¹³ Therefore the area targeted for ablation by the software may not be related to the pathophysiologic mechanisms underlying the arrhythmia. Moreover, it remains unclear whether functional rotors can be effectively ablated.²⁰⁹

Another possibility is the dependence of FIRM on a basket catheter that may not adequately adapt to individual variation in atrial geometry to provide optimal atrial coverage. It is inevitable that the basket catheter will bridge endocardial valleys and fail to fill out all the endocardial geometry. Also, panoramic mapping with the basket catheter provides insufficient spatial resolution due to poor tissue contact by the basket catheter electrodes, basket distortion, and interspline bunching, as well as inadequate electrode density to accurately detect rotors near the equatorial electrodes. This results in incomplete sampling of the atrial surface, potentially leaving mechanistically critical regions unmapped. To account for the missing electrograms (up to 50%) and limited spatial resolution of a basket catheter, extensive interpolation is required. Even within regions with adequate physical sampling, the signal quality is often too poor or the atrial coverage insufficient to perform phase analysis. The resulting activation maps are of such low resolution that it is difficult to precisely identify the site of any localized sources for ablation. This shortcoming would be expected to miss sources that may be present rather than falsely show sources. In addition, there are limitations, though minor, inherent in the representation of a complex 3-D structure as a 2-D rectangular grid of regularly spaced electrodes that assumes an ideal spherical fit of the basket catheter.^{16,209,210,214}

While significant questions remain regarding existence, methods of detection and meaning of rotors/focal sources detected by FIRM, the relatively high rate of AF termination to either AT/AFL or NSR and apparent improvement in mid-term freedom from recurrent AF in larger observational studies suggest the technique has validity.

ABLATION OF COMPLEX FRACTIONATED ATRIAL ELECTROGRAMS

Rationale

Evaluation of the complexity and frequency of intracardiac electrograms can help in understanding the pathophysiology of AF. Atrial electrograms during sustained AF have three distinct patterns: single potentials, double potentials, and complex fractionated potentials. Continuous propagation of multiple wavelets in the atria and wavelets as offspring of atrial reentry circuits has been suggested as the mechanism by which AF can be perpetuated without continuous focal discharge. Fractionated and continuous electrical activity has been assumed to indicate the presence of wave collision, slow conduction, or pivot points where the wavelets turn around at the end of the arcs of functional blocks. Thus areas of CFAEs during AF can potentially represent continuous reentry of the fibrillation waves into the same area or overlap of different wavelets entering the same area at different times, although the mapping

resolution to discern whether such rotors even exist in human AF is still limited.

Such complex electrical activity has a relatively short CL and heterogeneous temporal and spatial distribution. A relatively short CL may indicate the presence of a driver, analogous to the frequency gradient from the drivers or rotors to the rest of the atria observed in experimental models of AF, in which the central core of these rotors can have high-frequency electrical activity, whereas the periphery of the rotors displays complex electrograms because of wave break and fibrillatory conduction. Importantly, regions of CFAEs have been shown to remain spatially and temporally stable in individual patients, particularly when these regions were measured over several seconds, a surprising finding considering the earlier observation that a proposed underlying mechanism for AF is random reentry and that the reentrant wavelets are expected to meander.

Several studies suggested that areas of CFAEs are critical sites for AF perpetuation and can serve as target sites for AF ablation. It has been proposed that once CFAEs are eliminated by ablation, AF can no longer be sustained because the random reentry paths are altered or eliminated so that the fibrillation wavelets can no longer reenter the ablated areas. Whereas PV isolation targets the triggering foci, ablation of CFAEs targets the substrate for AF. However, some connections between both approaches probably exist. Data suggest that PVs and their antra are the key areas where CFAEs are located; these areas need to be ablated to achieve conversion of AF to NSR. It is thus very likely that many patients may respond to ablation in the PV regions because of both trigger elimination and substrate modification.

Mapping Complex Fractionated Atrial Electrograms

Mapping of CFAEs is performed during AF. In patients in NSR at the time of study, AF is induced by rapid atrial pacing, with or without isoproterenol infusion. During sustained AF, biatrial electroanatomic mapping is performed. The CS or RA appendage recording is used for electrical reference during mapping. Atrial CLs are monitored and recorded from the reference and mapping catheters. Sites with CFAEs can be tagged and associated with the atrial geometry created by the electroanatomic mapping system and thereby serve as target sites for ablation. During AF, the local activation time of the arrhythmia is of no value in guiding activation sequence mapping.

The definition of CFAEs has not been consistent. Initially, CFAEs were defined as: (1) fractionated atrial electrograms composed of at least two deflections or have a perturbation of the baseline with continuous deflection of a prolonged activation complex over a 10-second recording period; or (2) atrial electrograms with a very short CL (less than 120 milliseconds) averaged over a 10-second recording period (Fig. 15.49). More recently, CFAEs have been defined as having any of the following: (1) a magnitude of less than 0.25 mV; (2) a duration longer than 50 milliseconds with multiple (greater than 3) deflections from the isoelectric line; or (3) continuous electrical activity without an isoelectric line, verified visually. Some investigators, using unipolar mapping, defined fragmented potentials as electrograms exhibiting two or more negative deflections within 50 milliseconds. The limit of 50 milliseconds was based on the assumption that the atrial refractory period during AF and the interval between two successive fibrillation waves were 50 milliseconds or more.^{30,215}

An important limitation of this approach is that the visual appearance of CFAEs is variable, and they often are of very low amplitude (less than 0.25 mV); therefore their identification by visual inspection can be challenging and is highly subjective and investigator-dependent (Fig. 15.50). To improve the accuracy of CFAE mapping, custom software has been developed with algorithms that enable automated detection and tagging of areas of CFAEs and incorporated into either the CARTO

Fig. 15.49 Examples of Complex Fractionated Atrial Electrograms. Fractionated atrial electrograms with a very short cycle length, compared with the rest of the atria, were recorded in the left atrial (LA) roof. In the LA septum, fractionated electrograms with continuous prolonged activation complex were observed. See text for discussion. CS_{dist} , Distal coronary sinus; CS_{prox} , proximal coronary sinus.

Fig. 15.50 Fractionated Atrial Electrograms. Recordings from near ligament of Marshall (*Abl*) showing complex fragmented atrial electrograms (high-frequency, somewhat repetitive spikes [arrows]); these are not consistently present over the duration of the recording, whereas similar activity is intermittently seen in the His recordings (right atrial). or NavX EnSite electroanatomic mapping systems. This software offers valuable advantages in the detection, quantification, and regionalization of CFAEs.

Currently, the automatic algorithms are variable and are dependent on the recording technology (NavX and CARTO). In the CARTO system, fractionation is generally determined by the shortest complex interval between two consecutive deflections over a measuring period. The low-voltage window is usually programmed at 0.05 to 0.15 mV (to exclude

both noise and high-voltage signal from the analysis). The intervals between successive peaks falling within this window are measured. Intervals falling within a programmable duration (usually 60 to 120 milliseconds) are identified and the number of such intervals during the entire 2.5-second sampling window calculated; this is designated the “interval confidence level” (ICL). The assumption is that a greater number of short intervals between low-amplitude multi-deflection complexes in a given time duration (2.5 seconds) reflects more frequent

and repetitive CFAE and, hence, higher ICL. The CARTO software can also measure CFAE by either the “shortest complex interval” (which is the shortest interval found in milliseconds out of all the intervals identified between consecutive CFAE complexes) or the “average complex interval” (which is the average of all the intervals identified between consecutive CFAE complexes for each 2.5-second electrogram). CFAE areas are displayed on the whole-chamber map in a color-coded manner according to the degree of fractionated signals and their CLs for easier identification (eFig. 15.21).^{215–217}

The algorithm embedded in the EnSite mapping system uses a different principle, the “CFAE mean.” The CFAE mean is defined as the average time interval between consecutive deflections ($-dV/dt$) in a local AF intracardiac bipolar electrogram recorded over a specified length of time (5 to 8 seconds). The mean interdeflection time interval (i.e., the mean CL) is then projected onto the LA anatomic shell as a color-coded display. The shorter the mean CL, the more rapid and fractionated the local electrogram. Regions with mean CLs shorter than 120 milliseconds are considered to correspond to CFAE. To optimize algorithm accuracy, bipolar recordings are filtered at 30 to 500 Hz (to avoid sensing noise), electrogram width is set at less than 10 to 20 milliseconds (to avoid detecting far-field signals), and electrogram “refractory” period is set at 30 to 50 milliseconds (less than 30 milliseconds is regarded as nonphysiological). In addition, the baseline signal noise level is determined, and the peak-to-peak electrogram amplitude detection limit is set just higher than the noise level (typically, 0.03 to 0.05 mV) to minimize noise detection while allowing detection of CFAEs, which are typically of very low amplitude (less than 0.5 mV). This algorithm is probably most analogous to the “average complex interval” map from the CARTO software. Advantages of the EnSite system include an adjustable duration of recording from 1 to 8 seconds and the ability to record electrograms from multiple poles of several catheters simultaneously, which can potentially occupy a significant proportion of local AF CL.^{196,215–217}

Importantly, assessment of fractionated electrograms during AF requires a recording duration of at least 5 seconds at each site to obtain a consistent fractionation and accurate analysis. A small mapping catheter tip (4 mm), good atrial contact, and stable mapping catheter position for several seconds while mapping at each location are important to obtain high-quality recordings.

In general, CFAEs can be identified in most (80%) areas of the LA, but they appear to be predominantly located in the interatrial septum, LA roof, posterior wall, mitral annulus, and PV ostia. Less commonly, CFAEs are located in the RA, involving the septal region, crista terminalis, and CTI, as well as the CS os. Notably, patients with paroxysmal AF appear to have more CFAE sites identified around the PV ostia, whereas CFAEs detected in patients with persistent AF appear to be more evenly distributed over all areas of the LA. However, these findings have not been consistent across studies using different CFAE detection methods.

Target of Ablation

Atrial ablation is performed at atrial sites that harbor CFAEs characterized by the following: (1) low-voltage (range 0.04 to 0.25 mV) signals that have multiple potentials with continuous deflection of a prolonged activation complex; (2) stationary CFAEs that have temporal and spatial stability; and (3) short CL (less than 120 milliseconds) electrograms that occur repeatedly with a relatively stable frequency with or without multiple potentials as CFAEs. CFAE sites that are fleeting, have high amplitude, or have a relatively long CL (greater than 150 milliseconds) are not targeted by ablation.²¹⁸

The atrial septum, followed by the regions of the PVs, is the most common site for CFAEs. The most common localizations for termina-

tion and regularization of AF during CFAE ablation are the regions of the PV ostia, the interatrial septum, and the LA anterior wall close to the roof of the LAA.

After ablation of CFAEs in the LA, those in the CS and RA are targeted. RA ablation aimed at termination of AF can potentially offer a clinical benefit in patients with longstanding persistent AF, but it does not seem to improve outcome in patients with persistent AF of shorter durations.²¹⁸

Ablation Technique

The ablation typically begins at sites at which CFAEs have the shortest interval and preferably also have a high ICL. RF energy is applied using an 8-mm-tip or, preferably, an irrigated-tip catheter. Lower power output is applied in the CS and along the LA posterior wall. RF application is typically continued for 30 to 60 seconds at each site, aiming to eliminate or organize local electrograms.¹⁹⁶

The typical response of CFAE ablation procedures for persistent AF is a progressive increase in CL, and AF organizes into AFL or AT. It is rare for persistent AF to convert to NSR without changing to AT or AFL first.²¹⁸

Once AF organizes into AFL or AT, residual CFAEs around the tagged or previously ablated areas are sought and ablated. When the areas with CFAEs are completely eliminated, the focus or reentry circuit underlying the AT is mapped and specifically targeted by ablation. Administration of IV ibutilide can help lengthen the tachycardia cycle length (TCL), reduce residual fibrillatory conduction, and unmask the primary arrhythmia. If the arrhythmias are not successfully terminated by ablation or ibutilide, external cardioversion is performed.²¹⁸

When CFAE ablation is combined with PV isolation, some investigators recommend that CFAE ablation be performed before PV isolation, since the PV antra commonly harbor target CFAE. Others, however, recommend targeting CFAEs after, rather than before, PV isolation because that latter strategy can itself reduce the burden of CFAEs and minimize the consequent need for extensive LA ablation.^{196,218}

Endpoints of Ablation

The ablation endpoints when targeting CFAEs are uncertain. In most studies, the primary endpoints were complete elimination of the areas with CFAEs or organization and slowing of local electrograms, conversion of AF to NSR (either directly or first to an AT) for patients with persistent AF, or noninducibility of AF (with isoproterenol and atrial pacing) for patients with paroxysmal AF. When areas with CFAEs are completely eliminated, but arrhythmias continue as organized AFL or AT, those arrhythmias are mapped and ablated.³⁰

AF termination (conversion to AT or NSR) in patients with persistent AF can potentially be a challenging endpoint to achieve and generally requires very long procedure times. Reports demonstrated the limited ability of CFAE ablation to terminate persistent AF. Furthermore, although AF termination during ablation can potentially predict the mode of recurrence (AT vs. AF), its correlation with long-term success is still controversial. AF recurrence rates of more than 50% were observed even in patients in whom AF was terminated during CFAE ablation. Thus ablation of all areas displaying the electrogram of interest in the LA and CS can be a reasonable alternative endpoint when ablation fails to terminate AF.

Preliminary reports suggested the clinical utility of monitoring dominant frequency in real time to guide catheter ablation of AF. A critical decrease (11% or higher, measured in lead V₁ and the CS) of dominant frequency following CFAE ablation can potentially indicate adequate elimination of drivers of AF and is associated with clinical efficacy that is as high as when AF is terminated by ablation. However, these findings require validation in prospective studies.

eFig. 15.21 CARTO Maps of Complex Fractionated Atrial Electrograms (CFAEs). CFAE maps with registered left atrial (LA) CT surface reconstruction (shown as wire frame), shown in right anterior oblique (RAO) view (left-sided images) and posteroanterior (PA) view (right-sided images), in patients with paroxysmal atrial fibrillation (AF) (A) and persistent AF (B). The CFAE maps are color-coded, with red representing the highest interval confidence level (ICL) and purple representing the lowest ICL. Highly repetitive CFAE sites (ICL greater than or equal to 5) are tagged with light blue dots on the CFAE maps. As shown in this example, the highly repetitive CFAE sites are more likely located at the pulmonary vein (PV) ostia, interatrial septum, and mitral annulus area in patients with paroxysmal AF, whereas patients with persistent AF have highly repetitive CFAE sites predominantly identified on the LA posterior wall. FO, Fossa ovalis; LAA, left atrial appendage; LI, left inferior PV; LS, left superior PV; MV, mitral valve; RI, right inferior PV; RS, right superior PV. (From Scherr D, Dalal D, Cheema A, et al. Automated detection and characterization of complex fractionated atrial electrograms in human left atrium during atrial fibrillation. *Heart Rhythm*. 2007;4:1013.)

Outcome

Initial single-center studies using CFAE ablation as a stand-alone strategy for ablation of AF showed high success rates (up to 92% freedom from AF at 1-year follow-up after one or two ablation procedures). However, these results were not universally reproducible by other investigators, and several recent trials demonstrated that CFAE ablation alone is not a sufficient strategy for successful treatment of AF.

On the other hand, CFAE ablation can be of potential value as an adjunct strategy in combination with PV isolation, particularly in patients with persistent AF whose response to other ablation strategies is sub-optimal, as well as patients undergoing redo ablation for recurrent AF. However, even this approach has come under considerable scrutiny with the publication of randomized studies and meta-analyses showing no additional benefit conferred by CFAE ablation in conjunction to PV isolation as compared to PV isolation alone in patients with persistent or longstanding AF. Furthermore, in patients undergoing PV isolation plus CFAE ablation, there was no significant difference in outcome between those who had complete CFAE elimination and those who did not.^{146,196,219,220}

Notably, the mode of recurrence after CFAE ablation was predominantly organized AT or AFL, usually related to gaps within the ablation regions. Commonly, extensive CFAE ablation creates islands of noncontiguous lesions, leading to areas of slow conduction and predisposing to atrial macroreentry, thereby increasing the proarrhythmic potential.³⁰

The conflicting results of different studies can be partly the result of variability of mapping techniques, the inconsistencies in CFAE electrogram interpretations, differences in the type and size of the mapping electrode, and differences in the accompanying lesion set.²¹⁹ Furthermore, multiple algorithms and visual methods were used in different studies to guide CFAE ablation, which likely resulted in targeting different “substrate” sites, resulting in variable outcomes. In fact, in a recent study evaluating the diagnostic accuracy of several automated algorithms against manual determinations, CFAEs determined by automated bipolar algorithms were highly variable and correlated poorly with established AF substrate complexity measures and the agreement among them was poor. Furthermore, results of those algorithms were sensitive to inter-electrode spacing with an increase in CFAE detected with increased interelectrode distance.²¹⁶

Importantly, the benefits of AF substrate ablation have to be balanced against the potential risks in individual patients, especially given that CFAE ablation involves additional ablation lesions that can encompass extensive amounts of the atrial surface area, which can potentially compromise long-term atrial contractile function, produce arrhythmogenic atrial scarring, prolong procedure and radiation times, and increase risks of acute procedural complications.

In its current iteration, the CFAE ablation approach is limited by uncertainties regarding the mechanistic significance, efficacy, and the endpoint of the ablation strategy. The lack of standardization in CFAE definition and differences in mapping technologies and electrogram measurements, especially given the lack of comparative information for the current technologies, adds to the challenge. Furthermore, although multiple studies have found that ablation at sites of CFAEs could prolong the CL or terminate AF, their true significance in the pathophysiology of AF remains to be determined, and the sensitivity and specificity of CFAEs in identifying sites critical to perpetuation of AF are uncertain. The mechanistic relevance of all sites of CFAEs in specific clinical contexts and in individual patients can potentially differ. Some CFAE sites can simply result from passive atrial activation and reflect shortening in the AF CL, random collision of fibrillatory waves, wave disruption adjacent to rapidly firing foci or rotors, or nonuniform anisotropic conduction. In fact, significant spatiotemporal variability of CFAEs

exists across studies for uncertain reasons. Whether all CFAE sites need to be targeted for catheter ablation is still not known, and reliable criteria to distinguish active from passive electrogram patterns and define optimal ablation targets are lacking.²²¹

PULMONARY VEIN DENERVATION

Rationale

Experimental and clinical data suggest that the autonomic nervous system plays a critical role in the initiation and maintenance of AF. High-frequency stimulation of epicardial autonomic plexuses can induce triggered activity from the PVs and potentially shorten the atrial refractory periods, providing a substrate for the conversion of PV firing into sustained AF. Clinical studies found that ablation of the ganglionated plexuses located at the antra of the PVs (by specifically targeting the ganglionated plexuses or inadvertently during standard PV ablation procedures) can potentially reduce the risk of recurrence of AF.⁴¹

Localization of Ganglionated Plexuses

Autonomic inputs to the heart converge at several locations; these convergence points are typically embedded in the epicardial fat pads and form ganglionated plexuses that contain autonomic ganglia and nerves. There are seven major ganglionated plexuses, including four located in the LA around the PVs and one located within the ligament of Marshall. In the LA, the ganglionated plexuses are located around the antral regions of the PVs and in the crux (Fig. 15.51). The superior left ganglionated plexus is located on the roof of the LA, medial to the left superior PV, and often extends to the medial aspect of the LAA. The

Fig. 15.51 Left Atrial (LA) Ganglionated Plexuses (GPs). Schematic posterior view of the LA. The five major left atrial autonomic GPs and axons (superior left GP, inferior left GP, anterior right GP, inferior right GP, and ligament of Marshall) are shown. Hatched areas represent the anterior LA surface, and solid areas represent the posterior LA surface. The GPs innervate the adjacent pulmonary veins and surrounding atrium. Interconnecting neurons connect within and between GP. (From Stavrakis S, Nakagawa H, Po SS, et al. The role of the autonomic ganglia in atrial fibrillation. *JACC Clin Electrophysiol*. 2015;1:1–13.)

anterior right ganglionated plexus is located just anterior to the right superior PV and adjacent to the caudal end of the sinus node, and often extends inferiorly, to the region anterior to the right inferior PV. The inferior left ganglionated plexus is located at the inferior aspect of the posterior wall of the LA, 1 to 3 cm below the left inferior PV. The inferior right ganglionated plexus is also located at the inferior aspect of the posterior wall of the LA below the right inferior PV and may extend toward the area adjacent to the crux of the heart, where another atrial ganglionated plexus (the crux ganglionated plexus) is located.²²²

High-frequency electrical nerve stimulation allows for precise determination of the location, threshold, and predominance of the parasympathetic or sympathetic response of the ganglionated plexuses. The distal electrode of the mapping-ablation catheter is used to deliver high-frequency stimulation (1200 beats/min [20 Hz], at 12 to 24 V and pulse width 1 to 10 milliseconds) using a Grass stimulator (S88X dual output square pulse stimulator, Grass Instruments Division, Astro Med, Warwick, RI, United States). Tolerance of the conscious patient to the stimulation still must be determined because most reports have described use of this approach in deeply sedated patients.

High-frequency stimulation of a ganglionated plexus can elicit both parasympathetic and sympathetic responses. A parasympathetic response is typically elicited immediately (within 4 seconds) following stimulation, with return to baseline values on cessation of stimulation. A sympathetic response requires longer stimulation durations (8 to 10 seconds). A predominant efferent parasympathetic response to a 5-second high-frequency stimulation is defined as: (1) induction of sinus bradycardia (slower than 40 beats/min); (2) AV block (second- or third-degree AV block during sinus rhythm or a 50% or higher increase in mean R-R interval during AF); or (3) sudden decrease in blood pressure (20 mm Hg or greater reduction of systolic blood pressure). The sites of positive parasympathetic responses to high-frequency stimulation are marked on the electroanatomic map. If no response occurs, the catheter is moved to adjacent sites. It is important to limit high-frequency stimulation to only 2 to 5 seconds, to avoid eliciting a sympathetic response that would otherwise mask or attenuate the parasympathetic response (e.g., by facilitating AV conduction and increasing blood pressure).²²³

Before applying high-frequency stimulation to inferior ganglionated plexuses, it is important to ensure that the catheter tip is not close to the ventricle to avoid induction of VF. When high-frequency stimula-

tion is applied during NSR, AF generally occurs and usually terminates within seconds or minutes. Repeated stimulation usually results in sustained AF, at least in patients with a clinical history of AF.

Alternatively, ganglia identification and ablation can be accomplished by a purely anatomic technique without the need for specific localization with high-frequency stimulation. The suboptimal sensitivity of high-frequency stimulation in identifying *all* LA ganglionated plexuses can result in partial and nonhomogeneous atrial denervation. In addition, high-frequency stimulation commonly requires general anesthesia and carries the risk of repeated induction of AF. The anatomic approach is based on studies in humans demonstrating that the largest accumulation of PV-related cardiac neural structures is localized to the inferior and posterior surface of the roots of both left and right inferior PVs, as well as on the anterior surface of the root of the right superior PV.

Target of Ablation

During ablation of AF, the LA ganglionated plexuses are specifically targeted by ablation, as identified by high-frequency stimulation (rectangular electrical stimuli delivered at a frequency of 20 to 50 Hz for 5 seconds). Alternatively, ablation of ganglionated plexuses can be performed according to their anatomic locations instead of relying on the parasympathetic response to high-frequency stimulation, since the anatomic locations of the four major atrial ganglionated plexuses vary minimally among patients (Fig. 15.52).²²²

Ablation Technique

High-frequency stimulation is performed in the LA adjacent to the antral region of the PVs and the region of the LA crux. Once identified, the location of a ganglionated plexus is tagged on the electroanatomic map. Generally, the four major LA ganglionated plexuses can be identified and localized using high-frequency stimulation in the majority of patients; though it is not uncommon that one or more ganglionated plexuses cannot be identified, especially in patients with persistent AF. RF is delivered after all ganglionated plexus sites have been identified.

RF ablation is usually performed using an irrigated-tip catheter (25 to 35 W for 40 to 60 seconds). RF power and duration are reduced at sites close to the esophagus (15 to 20 W for 20 to 30 seconds). After each RF application, high-frequency stimulation is repeated immediately at the same site. If a positive parasympathetic response is still elicited,

Fig. 15.52 Anatomic Ablation of Left Atrial Ganglionated Plexuses (GPs). Segmented three-dimensional computed tomography of the left atrium is shown in a posteroanterior (A) and cranial right anterior oblique (B) views. Initially, circumferential antral pulmonary vein (PV) isolation is performed (*white dots*). Then, the ablation lesions were expanded (*red dots*) to cover the anatomic site of presumed GP clusters. *ILGP*, Inferior left GP; *IRGP*, inferior right GP; *LAA*, left atrial appendage; *LIPV*, left inferior PV; *LSPV*, left superior PV; *LSGP*, left superior GP; *RAGP*, right anterior GP; *RIPV*, right inferior PV; *RSPV*, right superior PV.

RF applications are repeated until such a response is no longer elicited. Notably, RF energy delivery does not usually elicit a parasympathetic response, even at sites with positive response to high-frequency stimulation. Thus the absence of an autonomic response should not prompt termination of RF application. Because there is experimental evidence that ablation of the inferior right ganglionated plexus can potentially attenuate the parasympathetic response of other ganglionated plexuses to high-frequency stimulation and hence render subsequent localization of other ganglionated plexuses challenging, it is preferred to stimulate and ablate the inferior right ganglionated plexus last.

When using an anatomic approach for localization of the ganglionated plexuses, the presumed ganglionated plexus clusters near the PV antra are targeted by RF ablation. Because the exact anatomic borders of ganglionated plexus clusters are unknown and their location can vary slightly in different patients, a relatively extensive regional ablation is performed by delivering RF energy at multiple sites in and around the presumed anatomic location of each ganglionated plexus. Using this approach, vagal reflexes can be observed in at least one-third of patients, typically within a few seconds of the onset of RF application (eFig. 15.22). When a vagal reflex is observed during RF application, RF energy should be delivered until these reflexes are abolished, or for up to 30 seconds. It is important to note that the specificity and sensitivity of eliciting such vagal responses during RF application are not known; similar responses can be triggered by pericardial pain during RF energy delivery. In addition, as noted previously, vagal responses are not usually observed during RF ablation directly over the location of the ganglionated plexuses identified by high-frequency stimulation or even while applying RF energy to the plexuses during epicardial surgical ablation.

Endpoints of Ablation

The endpoint of ablation is the abolition of all vagal reflexes evoked by high-frequency stimulation over the ganglionated plexus sites marked on the electroanatomic map. For anatomically guided atrial autonomic denervation, the endpoint of the ablation procedure is elimination of electrical activity (peak-to-peak bipolar electrogram less than 0.1 mV) in the specified areas and abolition of any vagal effects during RF energy delivery.

Outcome

At present, no reports have suggested that targeting of ganglionated plexuses as a stand-alone procedure will consistently terminate AF or prevent its reinitiation. On the other hand, several studies incorporating ganglionated plexus mapping and ablation with PV-based ablation procedures for the treatment of AF have produced promising, though variable, results. It is important to note that data suggest that the outcome of ganglionated plexus ablation guided by the vagal responses elicited by high-frequency stimulation is inferior to that guided by the anatomic locations of the ganglionated plexuses. It is likely that high-frequency stimulation underestimates the extent of the major atrial ganglionated plexuses and thus translates into significantly less autonomic denervation and subsequently a lower success rate. Currently, an anatomic approach to ganglionated plexus ablation is preferred.^{41,222}

Because the ganglionated plexuses are predominantly located near the PV antra, regions that are typically targeted by the different AF ablation strategies, whether the clinical benefits of ablation in these regions are related to selective ganglionated plexus modification and parasympathetic denervation, as opposed to interference with other AF-related mechanisms, is not known. On the other hand, some type of atrial denervation is likely to be inadvertently achieved after PV-based ablation procedures, which can potentially underlie, at least in part, the efficacy of these procedures. The conventional wide-area PV isolation

transects three of the four major atrial ganglionated plexuses (the superior left, anterior right, and part of the inferior right ganglionated plexuses), the ligament of Marshall, as well as many small clusters of autonomic ganglia and nerves. Nevertheless, ganglionated plexus responses still are commonly observed after extensive PV isolation (especially around the right inferior and left inferior ganglionated plexuses), and positive ganglionated plexus responses appear to predict an increased risk for AF recurrence after extensive PV isolation, especially in patients with paroxysmal AF.^{41,222,224}

It is important to note that the ganglionated plexuses reside in epicardial fat pads and can be difficult to ablate endocardially. Epicardial ablation during thoracoscopic surgery for AF can allow more selective ganglionated plexus ablation without ablating the underlying atrial myocardium. However, in a recent report, epicardial ganglionated plexus ablation during thoracoscopic minimally invasive AF surgery did not reduce AF recurrence. Also, parasympathetic denervation has been shown to recover after ganglionated plexus ablation, likely secondary to atrial neural resprouting and reinnervation, with the potential for future heightened sensitivity to remaining neural stimulation. This can potentially limit the long-term benefit of ganglionated plexus ablation.⁴²

ABLATION OF NON-PULMONARY VEIN TRIGGERS

Rationale

Although the PVs are the major site of ectopic foci initiating AF, non-PV ectopic beats can initiate AF. Several reports have identified non-PV triggers initiating AF in about 20% to 30% of unselected patients with paroxysmal and nonparoxysmal AF (range, 3% to 61% of patients undergoing AF ablation). The proportion of patients manifesting non-PV triggers is higher in those with previously failed PV isolation procedure. The non-PV ectopic beats can arise from the SVC (most common, especially in female patients), LA posterior wall (especially in patients with LA enlargement), crista terminalis, CS, ligament of Marshall, interatrial septum, or LAA. In addition, SVTs, such as atrioventricular nodal reentrant tachycardia (AVNRT) and atrioventricular reentrant tachycardia (AVRT), can be identified in up to 4% in unselected patients referred for AF ablation and can serve as a triggering mechanism for AF (see Fig. 15.3). Also, the presence of non-PV ectopic beats can play an important role in the recurrence of AF after PV isolation. Therefore targeting these foci can potentially decrease arrhythmia recurrence and improve procedural outcome.^{225–228}

Mapping of Non-Pulmonary Vein Triggers

Spontaneous activation of AF-initiating triggers is infrequently observed during EP procedures, especially given the heavy sedation or general anesthesia used in these procedures. Therefore provocative maneuvers are necessary in the vast majority of patients. Two different strategies are used to evaluate the potential existence of non-PV sources of AF: (1) pharmacological provocation to induce ectopic arrhythmogenic atrial activity; and (2) electrical cardioversion of spontaneous or induced AF.^{226,227}

The initial step is to locate the spontaneous onset of ectopic beats initiating AF in the baseline state or after high-dose isoproterenol infusion. A bolus of high-dose adenosine (12 to 24 mg) may also be used to provoke the spontaneous onset of AF. If spontaneous AF does not develop, intermittent atrial pacing (8 to 12 beats) at a PCL of 200 to 300 milliseconds from the high RA or CS is used to facilitate spontaneous initiation of AF after a pause in the atrial pacing. If spontaneous AF does not occur, burst pacing from the high RA or CS is used to induce sustained AF. After an episode of pacing-induced AF is sustained for 5 to 10 minutes, external cardioversion is attempted to convert the AF to NSR and observe the spontaneous reinitiation of AF.^{226,227}

eFig. 15.22 Vagal Reflex During Pulmonary Vein (PV) Isolation. Sinus rhythm is present at the beginning of the tracing; when radiofrequency (RF) energy is applied ("RF on"), blood pressure (BP) and heart rate decrease markedly (sinus bradycardia and nonconducted P wave). After energy is stopped ("RF off"), a short episode of atrial fibrillation ensues.

The onset pattern of spontaneous AF is analyzed, and the earliest ectopic site is considered to be the initiating focus of AF. The method used to provoke spontaneous AF is repeated at least twice to ensure reproducibility. P wave morphology on the surface ECG and atrial activation sequences from the high RA, HB, and CS catheters can predict the site of origin of the PACs. Mapping techniques are discussed in detail in **Chapter 11**.

Mapping and Ablation of the Ligament of Marshall

Rationale

The ligament of Marshall is an epicardial vestigial fold that results from the embryonic obliteration of the left anterior cardinal vein extending from the left subclavian/innominate vein to the CS. Occasionally, the left anterior cardinal vein remains open as the normal variant of persistent left SVC, but most commonly only its intracardiac portion remains patent as the vein of Marshall.^{229–231}

The ligament of Marshall contains the vein of Marshall, autonomic nerves, and muscle tracts (the Marshall bundle). The vein of Marshall originates at its junction with CS (at the level of the valve of Vieussens), courses along the epicardial surface of the lateral mitral isthmus, and extends to the epicardial surface of LA ridge that separates the LAA from the left-sided PVs. The transition from the extracardiac ligamentous structure to the intracardiac vein of Marshall occurs in the region between the left superior PV and base of the LAA.

The proximal portions of the Marshall bundles connect directly to the CS myocardial sleeves, while the distal portions of the myocardial sleeve extend upward into the PV and LA free wall, and insert into the epicardial region of the LA ridge between the LAA and left-sided PVs. The Marshall bundle provides a direct epicardial electrical bridge between the left lateral ridge and the CS muscle sleeve which bypasses the lateral atrial free wall. The ligament of Marshall also provides a conduit for parasympathetic and sympathetic nerves, connecting the extrinsic cardiac nervous system to the intrinsic cardiac ganglia, specifically the inferior left ganglion plexus.^{229–231}

The ligament of Marshall has been implicated in the initiation and perpetuation of AF and, thus, has been targeted by catheter ablation. Several attributes of the ligament of Marshall have been proposed to explain its mechanistic role in AF. The ligament of Marshall was shown to have electrically active myocardial tissue capable of generating focal automatic activity that can potentially contribute to the development of AF. Furthermore, multiple connections among the Marshall bundle, LA, and CS can potentially create paths for reentrant excitation, leading to more complex and rapid activations. In fact, electrograms recorded from the ligament of Marshall during AF often exhibit short CLs, high dominant frequency, and CFAEs. Furthermore, rich innervation of the ligament of Marshall, predominantly by sympathetic fibers at its PV junction and parasympathetic ganglia at its CS junction, has been observed. The ligament of Marshall serves as a vehicle of parasympathetic and sympathetic innervations that modulate electrical properties of atrial tissue and contribute to AF maintenance. High-frequency stimulation of the ligament of Marshall can induce AF, presumably by direct activation of such extrinsic nerves. Ablation of the ligament of Marshall can contribute to LA parasympathetic denervation strategies.^{229,232}

The ligament of Marshall should be considered as a source of paroxysmal AF, especially in young patients with a history compatible with adrenergic AF. In addition, whenever an ectopic beat is mapped to the region around the posterolateral mitral annulus or a left-sided PV ostium, an origin from the ligament of Marshall should be considered. The P wave morphology associated with vein of Marshall ectopic activity is characterized by an isoelectric P wave in leads I and aVL, positive in leads III, aVF, and V₂ to V₅, and it is similar to that seen with ectopic

beats arising from the left PVs. The P waves can be biphasic or negative in lead II.²²⁷

It is also important to recognize that the Marshall bundle can provide a direct electrical connection (epicardial bridge) between the LA ridge or left PVs and the muscle sleeves of the CS. This bridge can bypass the endocardial ablation lines across the lateral mitral isthmus or surrounding the left-sided PVs, rendering those lesion sets ineffective in achieving PV electrical isolation or bidirectional mitral isthmus block. In these situations, successful ablation necessitates ablation of the Marshall bundle.^{229,230,231}

Mapping the Ligament of Marshall

The ligament of Marshall can be mapped epicardially or endocardially. The endocardial approach involves cannulation of the CS (preferably via the SVC approach) with a 7 Fr luminal decapolar CS catheter. A venogram of the CS is obtained in the RAO 30-degree view to visualize the vein of Marshall and its ostium inside the CS. A 7 Fr luminal CS catheter is then directly engaged into the ostium of the vein of Marshall, and a 1.4 Fr mapping catheter is inserted into the inner lumen of the CS catheter and advanced toward the vein of Marshall.

However, cannulation of the vein of Marshall is not always successful because of various anatomic and technical reasons. In patients whose vein of Marshall either is not visible on a CS venogram or is visible but cannot be cannulated, the percutaneous (subxiphoid) epicardial approach may result in successful mapping and ablation (**Fig. 15.53**). This latter approach has the advantage of free catheter movement and is not limited by the size of the vein of Marshall. However, the endocardial approach is the best method for differentiating ligament of Marshall ectopy from other sources.

Because the ligament of Marshall can have multiple insertion sites in the LA free wall or near the PV ostium, it can be difficult to differentiate ligament of Marshall ectopy from PV or LA posterior free wall ectopy. Ectopy or rapid tachycardias arising from the PV typically demonstrate an early near-field potential on catheters placed within the PV and a late far-field electrogram consistent with LA activation. Often, the exit delay (interval between the early near-field and the late far-field potentials) exceeds the entrance delay seen in sinus rhythm with activation from the LA to the PV. Despite this exit delay, however, the earliest atrial activation should be in the perivenous area. In addition, if the earliest activation of ectopic beats is in the mid or distal CS and double potentials are present at those sites, the ligament of Marshall as the source of ectopy should be considered (**eFig. 15.23**).

In addition, the possibility of ligament of Marshall ectopy should be considered when the so-called triple potentials (a discrete sharp potential preceding the LA and PV potentials) are recorded around the PV ostium. Furthermore, in patients with ectopic beats from the ligament of Marshall, double potentials are present at the orifice of or inside the left PVs, and distal CS pacing can help differentiate the ligament of Marshall potential from the PV musculature potential. If the second deflection of double potentials is attributable to the activation of the ligament of Marshall, the interval between the CS os and the second deflection will be shorter during distal CS pacing compared with NSR. In contrast, if the second deflection is attributable to activation of the PV musculature, the interval between the CS os and the second deflection will be longer during distal CS pacing compared with NSR.²³⁰

Certain observations and pacing maneuvers can indicate electrical conduction occurring via the Marshall bundle, including (1) unexpected PV activation sequence during NSR, (2) unexpectedly early exit from PV ectopy, and (3) unexpected PV activation sequence during low-output CS pacing.²³⁰

During NSR, PV activation spreads from proximal (PV ostium) to distal. If earlier activation is seen deep within the PV than near the

eFig. 15.23 Ectopy From the Ligament of Marshall (LOM). Fig. 15.53 Two Different Approaches to Mapping of the Ligament of Marshall. (A) Vein of Marshall (VOM) visualized by balloon occlusion coronary sinus (CS) angiogram. A 1.5 Fr mapping catheter can be inserted via the CS into this VOM for endocardial mapping. (B) Epicardial mapping catheter inserted via a subxiphoid pericardial puncture. RAO, Right anterior oblique. (From Hwang C, Fishbein MC, Chen P. How and when to ablate the ligament of Marshall. *Heart Rhythm*. 2006;3:1505.)

ostium, a bypass of the ostium with direct activation of the middle or distal PV via the vein of Marshall is likely. Similarly, when ectopy from within the left-sided PVs results in unexpectedly early activation of the LA, whereby the PV potential at the focus of ectopy precedes the earliest LA activation site by less than 45 milliseconds, mapping of the ligament of Marshall should be considered.²²⁹

Pacing from the CS can help unmask conduction over the Marshall bundle. With high-output pacing in the mid-CS, there is capture of both the myocardium of the CS itself and the adjacent LA. With lower-output pacing, in most cases there will be capture of the myocardium of the CS only, with the LA activated from the CS through a CS-to-LA connection. In some patients, the CS-to-LA connection is small and discrete and, if the connection is not close to the site of pacing within the CS, there can be considerable delay between the CS myocardial electrograms and adjacent LA tissue electrograms (Fig. 15.54). This observation can be used to determine whether PV activation is occurring via the vein of Marshall. During low-output CS pacing, the LA is not directly activated. Because PV activation depends on LA activation, in most cases, when the LA electrogram is delayed, PV potentials also are delayed. When the time from stimulus to PV potential remains fixed regardless of whether direct capture of the LA occurs, PV activation is dependent only on CS muscular activation and a connection via the Marshall bundle very likely is present (see Fig. 15.54).

Importantly, electrical connections from left-sided PVs to the CS via the ligament of Marshall need to be suspected when electrical isolation of those veins fails despite complete circumferential antral ablation lines. This is often the case when PV potentials are recorded in distal left-sided PVs, while the antrum remains electrically silent. Similarly, when bidirectional block across the lateral mitral isthmus ablation line cannot be achieved despite extensive ablation, an epicardial electrical connection via the Marshall bundle bridging the endocardial linear lesion set in the mitral isthmus should be considered.

Ablation of the Ligament of Marshall

Ablation of the ligament of Marshall can be performed endocardially (via the LA), epicardially (via the CS or subxiphoid approach), or by ethanol infusion in the vein of Marshall.

Cannulation of the vein of Marshall with a mapping catheter and direct recording of the ligament of Marshall potentials from the vein of Marshall can be used as the anatomic targets for endocardial ablation and to confirm successful elimination of the ligament of Marshall potentials. Also, placing a ring catheter at the antrum of the left inferior PV can help guide and then confirm simultaneous isolation of the PV antrum and ligament of Marshall.

Even when cannulation of the vein of Marshall is not feasible, obtaining a CS venogram to visualize the vein of Marshall can be used as an indirect method to trace the possible route of the ligament of Marshall to help guide ablation (see Fig. 15.53). Traditionally, CS venography is performed utilizing a balloon catheter. The vein of Marshall is identified as a branch of the CS directed posteriorly (best shown in the RAO fluoroscopic projection) and superiorly. Recent reports described the feasibility of nonocclusive CS venography using open-irrigated ablation catheters (eFig. 15.24). The ablation catheter is initially positioned at the mitral annulus in the 4 o'clock position in the CS in the LAO view, and then gently pulled back to the proximal CS during manual contrast injection through the external irrigation lumen with a 5.0-mL syringe and without balloon occlusion. When the vein of Marshall is visualized, selective venography can be performed in the same manner after introducing the irrigation catheter into the ostium of the vein. The location of the ostium of the vein of Marshall can be marked in the 3-D electroanatomic map, and if the diameter is large enough, the ablation catheter is advanced into the vein to mark its anatomic course.²³¹

Ablation of the ligament of Marshall is performed at the LA endocardial aspect facing the epicardial vein of Marshall as tagged on the electroanatomic map or by the mapping catheter inside the vein. The site having the shortest distance from the LA endocardium to the ligament of Marshall is located along the inferoanterior aspect of the left lateral ridge, just below the left inferior PV ostium. RF energy application from the endocardium to this region eliminates ligament of Marshall potentials in more than 90% of the cases. Occasionally, ablation at more superior aspects of the left lateral ridge near the orifice of the left PV or in the LAA is required to eliminate all ligament of Marshall connections. Also, ablation targeting the vein of Marshall can be performed from inside the CS, typically around the ostium of the vein of Marshall.²³¹

eFig. 15.24 A Modified Technique of Selective Vein of Marshall Venography Using an Open-Irrigated Ablation Catheter. The left panel shows the left anterior oblique (LAO) projection, and the right panel shows the right anterior oblique (RAO) projection. Contrast dye injection through the ablation catheter (A) visualizing the oblique course of the vein of Marshall (arrows). A duodecapolar deflectable catheter (B) placed in the coronary sinus. A reference catheter (C) placed in the aortic valve cusp. A Lasso catheter placed in the left inferior pulmonary vein (D). (From Lee JH, Nam GB, Kim M, et al. Radiofrequency catheter ablation targeting the vein of Marshall in difficult mitral isthmus ablation or pulmonary vein isolation. *J Cardiovasc Electrophysiol.* 2017;28:386–393.)

Fig. 15.54 Identification of Vein of Marshall Activation Using Differential-Output Coronary Sinus (CS) Pacing. *Left panel*, During high-output CS pacing, both the left atrium (LA) and CS musculature are captured directly. *Right panel*, During low-output CS pacing, only the CS musculature is captured directly; the LA is activated from the CS through a CS to LA connection. In this case, the CS-LA connection is not close to the site of pacing within the CS; therefore considerable delay is observed between the CS myocardial electrograms and the adjacent LA tissue electrograms. Despite the delay in LA activation (as reflected by the interval between the pacing artifact and the LA electrograms) during low-output versus high-output CS pacing, the timing of left inferior pulmonary vein (LIPV) activation remains constant (as reflected by the fixed interval between the pacing artifact and the PV potentials in both cases), thus indicating that PV activation is occurring via the vein of Marshall and is independent of LA activation. ABL, Ablation catheter; CS_{dist}, distal coronary sinus; CS_{prox}, proximal coronary sinus.

Successful ablation is confirmed by the elimination of ligament of Marshall potentials along the entire length of the ligament (as recorded by the mapping catheter inside the vein of Marshall) and the presence of exit block between the ligament of Marshall and the LA during pacing from multiple sites within the vein of Marshall. Also, complete bidirectional electrical isolation (with entrance and exit block) of the entire left PV antrum confirms elimination of all connections to the LA, including the left PVs and ligament of Marshall.

Infrequently, endocardial ablation alone cannot eliminate all connecting fibers, as evidenced by the ability to still record ligament of Marshall potentials. In these situations, most of the remaining connections are located in the ridge between the anterior border of the left PVs and the posterior wall of the appendage. In some patients, the ridge can be as thick as 10 mm, and complete isolation still may not

be possible, even when using an irrigated-tip catheter and a high-power setting. In these difficult cases, a combined endocardial and epicardial approach can be used to ablate ligament of Marshall ectopy initiating AF and is associated with a higher success rate.

An alternative approach uses ethanol infusion to ablate the Marshall bundle. After the vein of Marshall is cannulated with a coronary vein sub-selection catheter, an angioplasty balloon is advanced over a guide-wire into the proximal vein of Marshall. A selective venogram is performed during balloon inflation. Then, two to four serial injections of ethanol are administered through the balloon lumen (1 mL 98% ethanol over 2 minutes). With each injection, the balloon is retracted slightly until the final injection is delivered at the most proximal junction of the vein of Marshall with the CS.²³²

Electrical Isolation of the Superior Vena Cava

Rationale

Histologically, atrial myocardial sleeves extend into the SVC for up to 2 to 5 cm. Those sleeves can harbor ectopic pacing cells that can spontaneously depolarize triggering atrial arrhythmias (eFig. 15.25). The SVC has been described as one of the most common non-PV AF sources (accounting for up to 55% of non-PV triggers of AF). The incidence of SVC triggers has been reported to be 2% to 12% of patients undergoing AF ablation. A recent study demonstrated that, in a subset of patients, the SVC plays a role in AF not only as a trigger but also as a driver. Of interest, long SVC sleeves (greater than 30 mm), large SVC potentials (greater than 1.0 mV), smaller LA size, and the coexistence of spontaneous typical AFL have been proposed as predictors of an arrhythmogenic SVC in patients undergoing ablation of paroxysmal AF.^{233–235}

Electrical isolation of SVC from the RA is likely a better strategy than focal ablation of ectopy inside the SVC; it obviates the need for detailed mapping of the exact origin of the ectopic focus, as well as the need for RF ablation inside the SVC, which may carry the risk of SVC stenosis. Nevertheless, injury to the sinus node and phrenic nerve remains a concern.

SVC isolation is recommended when SVC triggers are recognized after pacing maneuvers or isoproterenol infusion, and elimination of SVC triggers is associated with improved long-term maintenance of sinus rhythm after AF ablation. The value of empirical isolation of the SVC as an adjunctive strategy for AF ablation needs further evaluation. A limited number of randomized trials have been conducted to assess the role of prophylactic SVC isolation in addition to PV isolation in AF and arrived at conflicting results. A recent meta-analysis suggests that this approach does not provide any incremental benefit in AF recurrence compared to PV isolation alone. However, such an approach can potentially be beneficial in selected patients with paroxysmal AF and prevalent non-PV triggers.^{233,236,237}

Occasionally, a patient has a persistent left SVC; when present, this is often a source of AF and should be considered for electrical isolation, especially if AF continues after PV isolation or recurs after cardioversion. As noted, in most patients, the left SVC atrophies and becomes the vein or ligament of Marshall, coursing between the left PVs and LAA. A persistent left SVC may be suspected on preprocedure imaging (echocardiogram showing a very large CS; CT scan or magnetic resonance imaging [MRI] showing the persistent left SVC [eFig. 15.26]). Isolation of this structure can be performed much like right SVC isolation, using a multielectrode ring catheter in the left SVC at the level of the LAA. Care must be taken to avoid injury to the left phrenic nerve that may be adjacent to the left SVC more cephalad than the LAA.

Mapping of Superior Vena Cava Ectopy

Mapping of SVC ectopy is generally performed using a ring catheter, basket catheter, or 3-D electroanatomic mapping system (Fig. 15.55).

eFig. 15.25 Focal Atrial Tachycardia (AT) Originating From the Superior Vena Cava (SVC). The basket catheter is positioned in the SVC–right atrial (RA) junction. Bipolar recordings are obtained from the eight electrodes (1-2, 3-4, 5-6, 7-8) on each of the eight splines (A through H) of the basket catheter. During AT (*at left*), SVC potentials (*arrowheads*) precede RA potentials and also precede P wave onset on the surface electrocardiogram (*dashed line*). During RA pacing (*at right*), SVC potentials overlap with or follow RA potentials. CS, Coronary sinus.

eFig. 15.26 Persistent Left Superior Vena Cava (PLSVC). CT scan showing relationships of structures; note that the PLSVC is situated between the left superior (LSPV) and left inferior pulmonary veins (LIPV), and left atrial appendage (LAA); note also how the increased drainage results in marked enlargement of the coronary sinus (CS). The shape of the right atrium (RA) is drawn in due to poor opacification on the scan. IVC, Inferior vena cava; LAD, left anterior descending coronary artery; LV, left ventricle; RIPV, right inferior PV; RSPV, right superior PV; RSVC, right superior vena cava.

Fig. 15.55 Superior Vena Cava (SVC) Angiogram. Fluoroscopic right anterior oblique (RAO) views of SVC angiography with the ring (Lasso) catheter (at left) and basket catheter (at right) positioned at the SVC–right atrial junction (black arrowheads). Note that the size of the ring catheter is usually smaller than the circumference of the SVC, and repositioning of the ring catheter is typically required for circumferential mapping and electrical isolation of the SVC. Abl, Ablation catheter; CS, coronary sinus.

During NSR or atrial pacing, the intracardiac recordings from inside the lower level of the SVC (near the SVC-RA junction) frequently exhibit a blunted far-field atrial electrogram followed by a sharp and discrete SVC potential. At a more cranial level of the SVC, the SVC potential precedes the atrial electrogram during the SVC ectopic beat (Fig. 15.56). Furthermore, the intracardiac recordings in the higher SVC frequently exhibit double potentials. The first potential represents the SVC potential, and the second potential represents the far-field right superior PV potential. Simultaneous recordings from the right superior PV also exhibit a double potential during SVC ectopy. The recording from the right superior PV shows that the first potential is a far-field potential from the SVC, and the second potential is true activation of the right superior PV.

Electrical Isolation of the Superior Vena Cava

The SVC is isolated using the same technique and endpoint as used for segmental ostial PV isolation. Ablation targets the ostial portion of the breakthrough segments (electrical connections) connecting the RA to the SVC, identified as the earliest SVC potentials recorded from the ring catheter. Compared with PV isolation, it is easier to interrupt the conduction between the RA and the SVC. Most patients exhibit only two breakthrough sites. A ring or basket catheter can be used for mapping SVC potentials (see Fig. 15.56).

RF energy is applied at the level approximately 5 mm above the circumference of the SVC-RA junction (defined as the point below which the cylindrical SVC flares into the RA). Therefore the SVC-RA junction should be determined carefully before ablation. The SVC-RA junction can be confirmed by SVC venography (see Fig. 15.55), by ICE (eFig. 15.27), or by the electrical signals. SVC venography can be performed by placing a pigtail catheter at the top of the SVC and using a contrast injector (a total of 40 mL of contrast medium over 2 seconds) and biplane fluoroscopic views (RAO, 30 degrees; LAO 60 degrees). The overlapping of the anterior wall of the SVC and RA appendage is near the level of the SVC-RA junction.

The ring catheter is placed just above the RA-SVC junction at the level of the lower border of the pulmonary artery, as seen by ICE (see eFig. 15.27). The size of the ring catheter is usually smaller than the circumference of the SVC, and repositioning of the ring catheter is typically required for circumferential mapping and electrical isolation of the SVC (see Fig. 15.55). The SVC-RA junction exhibits an eccentric,

not a round, shape; thus the basket or ring catheter may not contact the wall well. Therefore one needs to manipulate the catheter to contact the whole SVC-RA circumference to confirm the presence or disappearance of SVC potentials.

The circumference of the SVC-RA junction is mapped (during NSR or atrial pacing) to determine the region of earliest SVC potentials recorded from the ring catheter. An isoelectric interval often separates the far-field RA electrogram and the near-field SVC potential. Not uncommonly, SVC potentials are fused with the far-field RA electrograms but can be identified by their high-frequency appearance. In addition, pacing maneuvers from the RA appendage and SVC can help discriminate SVC potentials from far-field RA electrograms by unmasking a decremental conduction property of the SVC-RA junction and separating those potentials from each other.

RF application in the SVC has potential risks of developing several complications, including SVC stenosis, sinus node injury and right phrenic nerve injury. Acceleration of the sinus rate during RF delivery is a sign that heat injury to the sinus node is occurring and should prompt discontinuation of RF application.

The SVC is located much closer to the course of the right phrenic nerve than are the right PVs, which explains the higher incidence of phrenic nerve injury during SVC isolation than during PV isolation. The right phrenic nerve courses immediately adjacent to the anterolateral wall of the SVC, but it veers posterolaterally at the level of the SVC-RA junction, where it is most vulnerable to injury during SVC isolation procedures. More inferiorly, it passes close to the junction of the LA to the right superior PV. Techniques to monitor right phrenic nerve function (as discussed previously) should be employed during SVC isolation. Early detection of nerve injury is essential to prevent permanent phrenic nerve injury since transient nerve injury occurs early and before permanent injury.²³⁸

Electrical Isolation of the Coronary Sinus

Rationale

The venous wall of the CS is surrounded by a continuous sleeve of atrial myocardium that extends for 25 to 51 mm from the CS os. This muscle is continuous with the RA myocardium proximally, but it is usually separated from the LA by adipose tissue. This separation can be bridged by muscular strands producing electrical continuity between the CS musculature and the LA. The muscular tissue in the wall of the

eFig. 15.27 Intracardiac Echocardiography for Electrical Isolation of the Superior Vena Cava (SVC). The intracardiac echocardiography catheter positioned in the high right atrium (RA) is used to guide positioning of the ring catheter at the RA-SVC junction (at the level of the lower border of the right pulmonary artery [RPA]). RSPV, Right superior pulmonary vein.

Fig. 15.56 Electrical Isolation of the Superior Vena Cava (SVC). This recording was obtained from a ring catheter positioned at the SVC–right atrium (RA) junction during electrical isolation of the SVC. (A) During atrial fibrillation, SVC potentials are observed at a cycle length (CL) longer than the atrial CL observed in the coronary sinus (CS) recordings. (B) The first complex is normal sinus, during which SVC potentials (blue shading) are observed following RA potentials (orange shading). The second and third complexes are premature atrial complexes originating from the SVC, during which SVC potentials precede RA potentials. (C) Radiofrequency energy application at a single site results in the disappearance of SVC potentials (at right) and complete SVC entrance block. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus.

CS appears to be electrophysiologically active, capable of spontaneous depolarization and mediating slow conduction, which can potentially contribute to initiation or perpetuation of AF.²³⁹

Ablation Technique

The muscular strands connecting the CS musculature to the LA connections are targeted by RF ablation for electrical isolation of the CS from the LA. Isolation of the CS is commenced along the endocardial aspect and completed from within the CS, as required. The ablation catheter is dragged along the endocardium of the inferior LA after looping the catheter to position it parallel to the CS catheter. After achieving a 360-degree loop in the LA, the catheter is gradually withdrawn initially along the septal area anterior to the right PVs and ablation commenced at the inferior LA along the posterior mitral annulus

from a site adjacent to the CS as progressing to the lateral LA (at the 4-o'clock position in the LAO projection). The endpoint is elimination of local endocardial electrograms bordering the mitral isthmus in an attempt to eliminate or prolong the CL of sharp potentials present within the CS (eFig. 15.28). Ablation within the CS is started distally (at the 4-o'clock position in the LAO projection) and pursued along the CS up to the ostium by targeting local sharp potentials at individual sites or as a continuous drag. During AF, ablation within the CS is performed at all sites showing persistent or intermittent rapid activity, either continuous electrograms or discrete electrograms displaying CLs shorter than the CL measured in the LAA. Finally, additional RF applications are continued around the CS orifice from the RA. CS disconnection is confirmed by the dissociation or abolition of sharp potentials in its first 3 cm.

eFig. 15.28 Electrical Isolation of the Coronary Sinus (CS). Intracardiac recordings illustrating CS electrograms during atrial fibrillation before, during, and after successful electrical isolation of the CS. Following complete electrical isolation, the local sharp potentials within the CS are eliminated. *ABL*, Ablation catheter; *CS_{dist}*, distal coronary sinus; *CS_{prox}*, proximal coronary sinus.

Electrical Isolation of the Left Atrial Appendage

Rationale

The role of the LAA in initiating and maintaining AF and atrial arrhythmias has increasingly been recognized. In some studies, approximately one quarter of patients presenting for repeat AF catheter ablation have inducible focal electrical activity that localizes to the LAA. Drivers of AF appear to originate from the LAA up to one-third of patients with longstanding persistent AF. Excision of the LAA is often proposed as a contributing factor to the high success rates for surgical AF ablation incorporating this approach. These findings have prompted some investigators to advocate empirical isolation of the LAA in this group of patients. However, electrical isolation of the LAA remains controversial as many investigators have found substantially lower prevalence of LAA sources of AF/AT, and until more evidence arises, LAA isolation needs to be considered only in selected cases.

Ablation Technique

The best strategy to achieve LAA electrical isolation remains to be determined. Segmental or circumferential isolation involves ablation at the ostial aspect of the LAA (similar to ostial isolation of the PVs). In contrast, wide-area isolation of the LAA incorporates linear ablation across the LA roof and lateral mitral isthmus in addition to an ablation line extending from the anterior mitral annulus to the left superior PV. The latter approach can potentially capture additional arrhythmogenic substrate, although it has been associated with a significantly higher risk of LAA thrombus formation.²⁴⁰

The endpoint of the ablation procedure is bidirectional electrical isolation of the LAA, defined as: (1) demonstration of entrance block—disappearance of all LAA potentials documented with a circular catheter placed within the LAA, regardless of the underlying cardiac rhythm; and (2) demonstration of exit block—LAA electric activity dissociated from the LA during LAA ectopy or pacing from within the LAA.

Recent studies suggest that electrical isolation of the LAA can improve long-term outcomes when combined to PV isolation in patients with longstanding persistent AF. However, achieving durable appendage isolation appears challenging and technically demanding. Importantly, LAA isolation (wide area isolation in particular) appears to be associated with an increased incidence of LA thrombus formation and stroke despite oral anticoagulation therapy, likely secondary to the lack of proper mechanical function in the LAA as a result of ablation. Therefore life-long anticoagulation or, preferably, percutaneous LAA closure (e.g., Watchman device) is recommended in these patients.^{241,242}

In addition, two epicardially based LAA exclusion devices have been demonstrated to produce electrical isolation of the LAA: the Lariat (SentreHEART); and the Atriclip (Atricure, Minneapolis, MN, United States). These devices result in progressive atrophy and fibrosis of the excluded appendage and also provide an effective mechanical barrier to thromboembolism. Whether such a procedure is a useful adjunct to PV isolation in patients with persistent AF is currently being investigated. In addition, isolation of the LAA with resultant loss of its mechanical activity deprives the patient of one of the benefits of NSR, LA transport function mediated to a significant degree by the LAA. Under these circumstances, a combination of trigger detection/elimination and modification of substrate (on which triggers act) can be reasonable.

Outcome

Several studies showed that non-PV ectopic beats play an important role in the recurrence of AF after PV isolation, and that AF ablation outcome can be improved if non-PV foci are detected and eliminated. Nonetheless, it is frequently difficult to map all non-PV triggers in a

single procedure. However, it is currently unclear whether an attempt should be made before and after PV isolation to observe the spontaneous or provoked ectopic beats initiating AF to evaluate for non-PV sources of this ectopy during initial and repeat ablation procedures. Also, given the fact that inducing those triggers is usually challenging and time consuming, it is uncertain whether prophylactic isolation of frequent anatomic sources of non-PV triggers (e.g., SVC, LA posterior wall, LAA, ligament of Marshall) is warranted, even without demonstration of the presence of such triggers.^{226,243}

Of note, the mere presence of non-PV triggers of AF appears to predict a higher risk of AF recurrence after catheter ablation. This is likely related to the difficulty in mapping and elimination of all triggers in the index procedure, particularly with the presence of multiple foci and the poor inducibility during EP testing.²²⁶

VOLTAGE-GUIDED SUBSTRATE MODIFICATION

Rationale

Atrial fibrosis plays an important role in the genesis and maintenance of AF. Myocardial fibrosis is associated with reduced intercellular coupling, slow and inhomogeneous conduction, dispersion of atrial refractory periods, and nonuniform anisotropic impulse propagation, which can promote reentry and perpetuate AF. The regional localization and the extent of LA scarring can be detected by late-enhancement CMR and correlates with reduced electrogram amplitudes on electroanatomic voltage mapping. Atrial scar burden predicts recurrence of AF following catheter ablation.^{200,244}

Recent studies have suggested a new, patient-tailored substrate modification strategy targeting fibrotic regions. Atrial scar (voltage) mapping can identify patients with more advanced disease and serve to guide more extensive ablation beyond PV isolation. This is in contrast to other substrate-based ablation strategies (such as linear ablation and posterior wall isolation) that applies ablation lesions empirically in all patients.

Target of Ablation

Voltage-guided substrate modification targets the potentially arrhythmogenic LA low-voltage zones identified on endocardial electroanatomic voltage mapping (atrial electrogram amplitude less than 0.5 mV) with ablation lesions aiming for complete box isolation of those areas or scar homogenization.^{200,244,245}

Ablation Technique

Initially, circumferential PV isolation is performed. Endocardial electroanatomic voltage mapping then is performed, preferably during NSR. In patients with persistent AF following PV isolation, electrical cardioversion is carried out to restore NSR before voltage mapping. In patients with refractory AF, voltage mapping may be performed during AF. Multielectrode catheters (e.g., PentaRay, Lasso, or mini-basket catheter) are often used to acquire high-density voltage maps.^{30,244,246,247}

Low-voltage areas are identified by the presence of three adjacent points exhibiting bipolar peak-to-peak voltage amplitudes less than 0.5 mV. Once identified, smaller low-voltage areas are ablated to achieve electric silence (bipolar electrogram less than 0.1 mV) and homogenize the fibrotic zone (Fig. 15.57). For the larger low-voltage areas, linear ablation along their borders is performed circumferentially (box isolation of fibrotic areas, BIFAs) to achieve complete electrical isolation of the fibrotic areas, an approach similar to that used for circumferential PV isolation (Fig. 15.58).^{30,244,246,247}

In addition, to prevent the formation of narrow, potentially proarrhythmic residual isthmuses, linear ablation is performed to connect the BIFA ablation lines or scar areas to the closest ablation line or to

Fig. 15.57 Voltage-Guided Substrate Modification for Atrial Fibrillation. Left atrial (LA) voltage maps in four different patients (A–D) showing variable severity and localization of LA fibrosis. (A) Regional low voltage zone ablation on the LA anterior wall and roof, creating anterior and roof lines. (B) Low voltage zone ablation of the anterior wall; a strategic roof line was added to prevent a secondary atrial tachycardia. The gold tags show the lesions creating the roof line. (C and D) Low voltage zone ablation on the septal wall and posterior wall, respectively. The white and blue tags show the ablated regions in the pulmonary vein isolation, and the brown tags show the ablated regions in the low voltage zones. The red tags indicate the termination sites of the reinduced atrial fibrillation. AP, Anterior-posterior; LAO, left anterior oblique; PA, posterior-anterior; RAO, right anterior oblique. the mitral annulus. When an ablation line is created, the achievement of bidirectional block across the line should be verified.^{30,244,246,247}

Endpoint of Ablation

The endpoint of the box isolation (BIFA) is complete electrical isolation of the low-voltage areas, as confirmed by entrance and exit block. Scar homogenization aims at elimination of all electrograms and achieving electric silence (bipolar electrogram less than 0.1 mV) within the low-voltage zone, as confirmed by voltage remapping. Whenever linear ablation is performed across narrow isthmuses, bidirectional block across the ablation line should be sought, as confirmed by double potentials along the line and activation sequence mapping during atrial pacing from both sides of the line.^{30,244,246,247}

Outcome

Substrate ablation targeting low-voltage areas in the atrium has been emerging as a potential approach to enhance the efficacy of AF ablation, particularly for persistent AF. Recently, several small studies demonstrated a potential benefit for regional voltage-guided LA substrate modification in conjunction with PV isolation in patients with persistent AF and those undergoing redo ablation for paroxysmal AF. In a recent meta-analysis, this approach was found significantly more effective than PV isolation alone or PV isolation plus conventional empirical linear ablation in patients undergoing catheter ablation of nonparoxysmal AF. Notably,

voltage-guided substrate modification appears to have lower proarrhythmic potential (as demonstrated by the lower incidence of postablation AT rate) as compared to empirical LA linear ablation strategies.²⁴⁴

However, the best methods of defining scar (CMR vs. voltage mapping) and techniques for modifying scar regions (box isolation vs. scar homogenization) are yet to be determined. In addition, voltage-guided ablation strategies share the same limitations as those encountered during voltage mapping. The optimal voltage cutoffs for definition of abnormal LA substrate remain uncertain. Further, the measured voltage also depends on the rhythm (NSR vs. AF), and the electrode contact with tissue, among other variables. Also, far-field potentials can potentially obscure voltage maps.²⁴⁸

OUTCOME AND EFFICACY OF CATHETER ABLATION OF ATRIAL FIBRILLATION

There are several hypothetical benefits of ablation of AF and restoration of sinus rhythm: improvement in quality of life, reduction of stroke risk, reduction in heart failure risk, and improved survival. Cumulative evidence suggests that catheter ablation is superior to antiarrhythmic drug therapy in the management of paroxysmal and persistent AF in terms of improved AF-free survival, AF burden, and quality of life. However, evidence is insufficient to determine whether AF catheter ablation reduces all-cause mortality or stroke. Therefore the primary

Fig. 15.58 Voltage-Guided Ablation of Atrial Fibrillation. Left atrial voltage maps in four different patients (A–D) showing variable severity and localization of left atrial fibrosis. Box isolation of the fibrotic areas is performed in all cases with connection to the preexisting PV isolation lines. Color coding: red for substantially reduced voltages less than 0.5 mV and purple greater than 1.5 mV. LPV, Left pulmonary veins; RPV, right pulmonary veins. (From Kottkamp H, Berg J, Bender R, et al. Box isolation of fibrotic areas (BIFA): a patient-tailored substrate modification approach for ablation of atrial fibrillation. *J Cardiovasc Electrophysiol.* 2016;27: 22–30.)

justification for an AF ablation procedure at this time is the presence of symptomatic AF.¹

Success Rates

With operator experience, greater consistency in the technique, and the advent of more advanced mapping and ablation technologies, AF ablation has proved to be very effective treatment for symptomatic AF. Reportedly, current techniques of RF catheter ablation can achieve a 60% to 90% improvement in selected patients with medically refractory AF, with similar success rates being reported by several different groups. Although success rates are not perfect, they are two- to threefold better than anything achievable by antiarrhythmic medications. Furthermore, successful control of AF by ablation seems to be durable, given the long follow-up reported by some groups and the observation that most recurrences tend to occur early in the follow-up period, and they only infrequently occur late after ablation.²⁴⁹

It is important to note that significant discrepancies in success rates have been reported for similar procedural techniques for catheter ablation of AF by different centers. These discrepancies can potentially arise from several factors, including variation in study design, different patient population characteristics (age, cardiac disease, LA size), different types of AF (paroxysmal vs. persistent vs. longstanding), differences in follow-up duration and strategy, and differences in definition of success (complete freedom from all atrial arrhythmias vs. AF vs. symptomatic arrhythmias, with or without antiarrhythmic agents). Also, the efficacy

of AF ablation can be largely influenced by the operator's experience and the volume of ablations.

Furthermore, consideration needs to be given to the adoption of a subclassification of AF based on clinical criteria if the magnitude of the therapeutic impact of catheter ablation on patients' quality of life is to be meaningfully assessed. For a patient whose condition is transformed from a predominant pattern of highly symptomatic persistent AF before ablation, to a pattern of asymptomatic or symptomatic short-lived episodes of transient AF (lasting a few minutes) after ablation, the procedure could be deemed clinically successful. In contrast, a binary outcome analysis limited to whether a patient has any recurrence of AF at any time or is free of AF recurrence would classify the ablation as a failed procedure, and any clinical benefit to the patient would not be recognized.

Ongoing clinical trials (CABANA [Catheter Ablation Versus Antiarrhythmic Drug Therapy for Atrial Fibrillation] and EAST [Early Therapy of Atrial Fibrillation for Stroke Prevention Trial]) should provide new information regarding the efficacy of catheter ablation as compared to antiarrhythmic drug therapy as a primary strategy for control of AF for reducing total mortality and other secondary outcome measures, and regarding the value of early application of a rhythm-control therapy (with ablation, antiarrhythmic drug therapy, or both) in reducing the risk of stroke, cardiovascular death, or heart failure.

Several clinical variables can potentially predict lower success rates of AF ablation, including larger LA size, persistent versus paroxysmal

AF, longer AF duration, older patient's age, female gender, number of antiarrhythmic drugs failed before ablation, higher CHADS₂ and CHA₂DS₂-VASc scores, and the presence of hypertension, untreated obstructive sleep apnea, coronary artery disease, and metabolic syndrome. In addition, several reports attempted to identify preprocedural markers of the extent of pathological atrial tissue remodeling and predictors of success (e.g., quantification of atrial fibrosis and scar burden on CMR and severity of LA enlargement) that may help improve selection criteria. Although the LA size and duration of longstanding AF, among other markers, can potentially predict lower procedure success rates, most of these markers do not adequately distinguish subjects in whom ablation should categorically be avoided. The question of how to identify patients in whom structural remodeling and scarring have become irreversible and it is too late to intervene remains unanswered, although preliminary data from cardiac CMR, assessing the degree of LA scarring, hold promise. Nonetheless, it is now well recognized that intervention relatively early in the course of persistent AF helps achieve a better outcome.¹

Ablation of Paroxysmal Atrial Fibrillation

In the setting of paroxysmal AF, RF ablation of AF (generally circumferential antral PV isolation with little to no adjuvant ablation) was found superior to antiarrhythmic drug therapy in several studies, with success rates (freedom from arrhythmias at 12 months) ranging from 59% to 89% (compared to 5% to 23% with antiarrhythmic drug therapy). In many of these studies, a single repeat ablation procedure was required in 10% to 25% of patients. Circumferential antral PV isolation is more effective than segmental ostial PV isolation. The role of adjunctive substrate-based ablation techniques (linear ablation, CFAE ablation, voltage-guided substrate modification, and vagal denervation) is controversial, but these approaches appear to have little value, if any, over antral PV isolation alone in patients with paroxysmal AF.¹

Ablation of Nonparoxysmal Atrial Fibrillation

In patients with persistent AF, circumferential antral PV isolation offers success rates of 32% to 67% after a single procedure and 59% to 88% after multiple procedures. In a meta-analysis of recently published studies using the latest technology, PV isolation alone resulted in a 67% freedom from recurrent AF in the 12 months after ablation in patients with persistent AF and minimal structural heart disease.^{1,249}

Purely anatomic techniques of PV ablation have been found to be inferior to techniques that rigorously confirm complete PV electrical isolation (single procedure success rate of 27% vs. 57% at 2 years of follow-up). CFAE ablation as a stand-alone strategy appears inadequate for successful treatment of AF (pooled success rate of only 26%). Similarly, evidence for rotor ablation efficacy is observational and has not been widely reproduced. Segmental ostial PV isolation is inadequate for arrhythmia control, with single-procedure, drug-free success rates of approximately 22%, and multiple-procedure success rates lower than 55%.

Importantly, regardless of the ablation strategy, multiple procedures appear to be required in nearly half of patients with nonparoxysmal AF. Nonetheless, maintenance of NSR is significantly higher with ablation as compared to antiarrhythmic drug therapy.

Impact on Quality of Life

Patients with AF have substantially impaired quality of life, comparable to patients with coronary artery disease and congestive heart failure; hence, symptomatic improvement is the main objective in the treatment of AF patients. Several studies have demonstrated greater improvement in symptoms and quality of life scores with catheter ablation compared with drug therapy. Those improvements were observed whether abla-

tion was used as a first-line or second-line therapy in patients with symptomatic AF.

It is important to note that, although improvements in quality of life scores are often related to reduction of arrhythmia burden, the quality of life improvement after AF ablation is not entirely dependent on efficacy of the ablation procedure. In fact, up to 65% of patients with documented recurrences of AF after ablation exhibit improvement of symptoms during the AF episodes and report significant improvement of the physical component of the quality of life. Reduction of symptomatic episodes after ablation can potentially arise from a placebo effect or autonomic denervation. It is worth noting that the improvement of quality of life observed postablation appears to fade with time.²⁵⁰

Impact on Cardiac Structure and Function

Restoration of sinus rhythm is expected to improve atrial mechanical function as compared with AF; however, the impact of catheter ablation of AF on LA transport function is still under investigation. Several studies demonstrated an increase in the LA voltage and a decrease in the LA volume following AF ablation. Reversal of atrial electrical remodeling following restoration of NSR can happen within 1 week, and reverse structural remodeling has been demonstrated by imaging studies during long-term follow-up after successful AF ablation.

On the other hand, extensive ablation of atrial tissue replaces myocardium with scar and prolongs intraatrial conduction, which can potentially result in asynchronized contraction of the LA, possibly attenuating atrial contractile performances. The decline in LA systolic function appears to be strongly correlated with the volume of RF ablation scar. Furthermore, extensive septal ablation can potentially damage the Bachmann bundle and delay LA activation, attenuating LA contribution to LV filling, especially when the latest activity in the LA occurs after the QRS, because of closure of the mitral valve before completion of LA contraction. It is likely that the smaller the surface area occupied by scar tissue, the greater the probable benefit for atrial contractile function.

In addition, pulmonary hypertension with LA diastolic dysfunction and preserved atrial systolic function (so-called "stiff LA syndrome") has been observed in 1.4% of patients following AF ablation. Patients with extensive atrial scarring, small LA (45 mm or less), diabetes mellitus, obstructive sleep apnea, and high LA pressure seem to be more prone to develop this syndrome. Symptomatic patients manifest with dyspnea and congestive heart failure. Further refinement of techniques to identify sites crucial for maintenance of AF or subsequent AT on an individual basis is therefore necessary to minimize the extent of LA injury and to maximize the mechanical benefit of catheter ablation therapy for AF.

In patients with heart failure and LV systolic dysfunction, AF ablation was shown to produce significant improvement in LV function, LV dimensions, symptoms, exercise capacity, and quality of life compared with a medical rate control strategy. In one report, catheter ablation strategy resulted in an early improvement in LV function, which was evident at 1 month and was sustained at 1 year compared with the rate control group. Of note, restoration of NSR by AF ablation was found to improve LV function even in patients with preserved LV systolic function. Therefore prior to accepting a rate control strategy, catheter ablation should be considered in patients with heart failure and drug-refractory AF, whether or not the cardiomyopathy is suspected to be related to rapid ventricular rates during AF. In fact, data have also demonstrated that adequate rate control alone is insufficient to prevent AF-mediated cardiomyopathy in a subset of AF patients.¹³⁹

Impact on Stroke Risk

Several observation studies have investigated the long-term risk of stroke after ablation and suggested that successful ablation of AF can lower

the risk of stroke via maintenance of NSR. These studies, however, mainly included patients with a low to intermediate risk of stroke, and incorporated relatively short follow-up intervals with variable utilization of oral anticoagulation. The potential benefits of AF ablation on stroke risk reduction have not been confirmed by large prospective randomized trials and therefore remain unproven.

Recurrence of Atrial Tachyarrhythmias

Recurrences of atrial tachyarrhythmias (AF, AFL, or AT) are common, observed in more than 50% of patients following catheter ablation, regardless of the ablation technique. The incidence of recurrent AF seems to be higher in patients with persistent AF (47%) as compared with paroxysmal AF (33%), in patients older than 65 years (48%) versus patients younger than 65 years (28%), and in patients with structural heart disease (47% to 74%) versus patients without structural heart disease (29% to 50%). Less consistent predictors of AF recurrence include the presence of comorbidities such as hypertension, sleep apnea, and diabetes.

The incidence of AF recurrences increases with increasing follow-up duration and intensity of cardiac monitoring. Considering the intermittent nature of the arrhythmia and the inconsistency of symptoms, the exclusive reliance on patient reporting of symptomatic recurrences results in an underestimation of the rate of arrhythmia recurrence. To obtain reliable information about the success of AF ablation, repeated ambulatory monitoring with automatic detection of arrhythmias is necessary.

Recurrences of atrial arrhythmias after ablation are generally classified according to the timing of first occurrence following the index ablation procedure: (1) early recurrence (within 3 months); (2) late recurrence (from 3 months to 1 year); and (3) very late recurrence (more than 1 year). Most arrhythmia recurrences occur within the first 12 months, and most patients who remain free of AF at 1 year after ablation are likely to remain in NSR at long-term follow-up. Among patients who develop recurrent AF, approximately 76% do so within the first 6 months after ablation, 86% by 12 months, and 92% by 24 months. Although there continues to be an ongoing risk of recurrent AF, new recurrences of AF are infrequent beyond 12 to 24 months following ablation.

Early Recurrences

Early recurrences of atrial arrhythmias have been reported in up to 50% of patients; usually, they peak within the first few weeks and then gradually decrease to lower levels in the period of 3 months after ablation.

The mechanism of early postablation AF is unclear but seems to be different from that of the patient's preablation arrhythmia. Several mechanisms have been implicated, including local inflammation in response to RF thermal injury or pericarditis, systemic inflammation, heightened adrenergic tone, changes in medicines, fluid and electrolyte imbalances, and a delayed therapeutic effect of RF ablation likely attributable to lesion growth or maturation.¹

In addition, failure to identify and modify AF triggers (e.g., incomplete isolation of the PVs, recovery of conduction in a previously isolated PV, or untreated non-PV foci triggers) can manifest with early AF recurrences. In fact, early recurrences of atrial arrhythmias following AF ablation have been reproducibly associated with long-term arrhythmia recurrence. The rates of late recurrences are significantly higher in patients with early arrhythmia recurrences than in those without (54% vs. 7%).

Nevertheless, it is important to recognize that early recurrences of atrial arrhythmias do not necessarily imply long-term procedural failure. In many patients, early atrial arrhythmias resolve completely upon

resolution of the transient factors promoting early arrhythmia recurrences; up to half of patients who experience such early recurrences remain free of atrial arrhythmias during long-term follow-up. Therefore current guidelines recommend a "blanking period" of 3 months after the initial ablation, during which re-ablation in response to arrhythmia recurrence is not recommended.^{1,148,251}

Although early arrhythmia recurrences are an independent predictor of long-term arrhythmia recurrence, the strength of this association differs depending on timing of the arrhythmic events within the blanking period, with later onset (in the second and third months after ablation) being more predictive. In a report of patients with early recurrences of atrial arrhythmias, the incidence of arrhythmia recurrences beyond the blanking period was 44% when the first episode of atrial arrhythmias was in the first month, 69% if in the second month, and 98% if in the third month. Therefore some investigators have suggested limiting the blanking period to the first 1 to 2 months and postponing redo procedures until after this time.²⁵² Patients experiencing recurrences of atrial arrhythmias only in the first 2 weeks following ablation are as likely to achieve long-term ablation success as patients who did not experience any arrhythmic events. This is consistent with the studies demonstrating that transient proarrhythmic factors following the ablation procedure (including inflammation and autonomic dysfunction) typically resolve by one month. Arrhythmias occurring after the resolution of inflammatory changes likely reflect reestablishment of the original AF substrate.²⁵¹

Late Recurrences

Late recurrences of atrial arrhythmias can be observed in 25% to 40% of patients. Beyond the early postablation period, recurrent AF following PV isolation is predominantly caused by PV triggers originating from previously isolated PVs rather than non-PV foci. Recurrence of PV-LA conduction in one or more PV is almost universal (more than 80%).¹

Very Late Recurrences

Very late AF recurrences, developing after an initial freedom from AF during the first year following ablation, are observed in approximately 4% to 10%. These recurrences appear still to be triggered by foci from reconnected PVs in most cases; however, non-PV triggers can also play an important role. The insidious and progressive arrhythmogenic substrate formation during a period of apparent AF elimination is also a likely cause.

Management of Recurrent Atrial Fibrillation

As noted previously, administration of antiarrhythmic drug therapy to patients who undergo catheter ablation for AF can decrease early recurrence of atrial arrhythmias. However, the long-term risk of AF recurrence does not seem to be affected by early, prophylactic, short-term use of antiarrhythmic drugs. Nonetheless, because early recurrences of AF are common and do not necessarily predict long-term recurrences, some operators choose to treat all patients with suppressive antiarrhythmic drugs during the first 1 to 3 months following ablation, a strategy that can potentially help decrease morbidity related to symptomatic arrhythmia episodes and the need for cardioversion or hospitalization. In patients discharged with antiarrhythmic drug therapy, such therapy is discontinued if no recurrence of AF is observed after 1 to 3 months.¹

For early AF recurrences (occurring within the blanking period), a pharmacological rhythm control strategy can be considered. In patients discharged without antiarrhythmic drug therapy who develop paroxysmal episodes of AF, antiarrhythmic drug therapy often is initiated unless the patient is satisfied with the extent of symptomatic improvement. For persistent AF, the early restoration of NSR can improve the

likelihood of long-term maintenance of NSR, regardless of when the arrhythmia first recurs after the ablation procedure. As noted above, it is recommended to avoid redo ablation within the blanking period (especially within the first 1 to 2 months postablation) until ensuring that the arrhythmias are not related to the transient postablation proarrhythmic milieu. Nonetheless, re-ablation can be considered for highly symptomatic atrial arrhythmias that prove to be refractory to medical therapy.

Management decisions for AF recurring beyond the blanking periods should consider the arrhythmia burden and impact on patient's quality of life. A rhythm control strategy is recommended for persistent or symptomatic paroxysmal AF. If AF recurs following discontinuation of antiarrhythmic medications, it is common practice to reinstitute the antiarrhythmic drug. The index ablation procedure for AF can be partially effective and allow a patient with AF that was previously refractory to antiarrhythmic drug therapy to become responsive to drugs.

Redo ablation can also be considered for late AF recurrences, especially when antiarrhythmic drug therapy is not effective, not tolerated, or not preferred. However, it is important to recognize that recurrence of AF after the initial ablation procedure should not prompt automatic redo ablation. Because improvement in quality of life and reduction of symptoms are the main goals of ablation, the mere recurrence of AF after the initial ablation procedure should not be the only basis for recommending re-ablation. Reassessment of the degree of improvement the patient experienced following the initial procedure, the severity of symptoms during AF recurrences, the burden of AF, and the potential response to antiarrhythmic drugs should all be taken into consideration before recommending re-ablation. Some patients experience a substantial palliative effect of ablation whereby AF recurrences cause minor or no symptoms, whereas others achieve satisfactory control with antiarrhythmic drugs that previously failed in the treatment of AF. Many of those patients may prefer to continue pharmacological therapy rather than undergo a repeat ablation procedure. However, in other patients it can be desirable to eliminate all arrhythmias and possibly eliminate antiarrhythmic drug therapy; hence, repeat ablation may be considered in the setting of AF recurrence following the initial procedure. In general,

recurrences of AF or AT after an initial AF ablation procedure lead to a repeat ablation procedure in 15% to 50% of patients.¹

When a repeat ablation procedure is performed for recurrent AF, the initial approach is to assess each PV for reconnection. In most patients, recovery of PV-LA conduction is observed in one or more PV, and PV reisolation is recommended and is frequently sufficient. This can be accomplished by selective ablation targeting only the segment of the PV circumference in which the PV reconnection is detected (Fig. 15.59). Alternatively, ablation can be performed circumferentially around the antrum of the reconnected PV or around all PVs, whether reconnected or isolated at baseline (especially when the original AF ablation strategy did not incorporate circumferential antral PV isolation).²⁵³

In the minority of patients with recurrent AF despite chronically isolated PVs, several ablation strategies have been proposed, including (1) ablation of provoked non-PV triggers; (2) empirical electrical isolation of common sources of non-PV triggers (e.g., SVC, CS, LA posterior wall, ligament of Marshall, LAA); (3) ablation of autonomic ganglia; (4) empirical linear ablation (LA roof line, mitral isthmus line, CTI line, posterior wall box lesion); or (5) substrate modification guided by FIRM mapping, CFAE mapping, or voltage mapping. However, definitive evidence of the benefit or superiority of any of these techniques over the others is lacking. Patients with AF despite PV isolation likely represent a population with more complex underlying mechanisms of arrhythmia, and the success of repeat ablation in these patients is modest, regardless of the ablation strategy employed.^{1,253,254}

Atrial Tachycardia and Flutter Following Ablation of Atrial Fibrillation

LA tachycardia or flutter is a known complication of catheter-based therapies of AF, accounting for about half of all atrial tachyarrhythmias observed following ablation. Originally reported in association with LA scar following mitral valve or maze surgical procedures, several reports demonstrated focal and macroreentrant ATs occurring after linear LA ablation and circumferential and segmental PV isolation, with an incidence ranging between 2% and 50%. The incidence seems to be lower following segmental ostial PV isolation than circumferential

Fig. 15.59 Reconnection of Previously Isolated Pulmonary Veins (PVs). Electroanatomic (Rhythmia) activation map of the left atrium and PVs (left anterior oblique view) is performed during pacing from the distal coronary sinus. Red color indicates already activated sites; purple color indicates sites activated late; and color spectrum in between shows the location of the propagating activation wavefront. (A) Conduction into the left superior PV (LSPV) occurs through a conducting gap (yellow dot, arrow) at the inferomedial aspect of the previous circumferential antral ablation line. (B) Conduction of the left inferior PV (LIPV) is also intact, by more delayed than that into the LSPV. Reconnection of the LIPV occurs through a gap at the carina between the left-sided PVs (yellow dot, arrow). (C) After selective ablation targeting the gaps in the previous ablation lines, activation mapping reveals electrically silent left sided PVs (gray color) and complete electrical isolation. LAA, Left atrial appendage; MA, mitral annulus.

PV isolation and much higher following circumferential or linear LA ablation (more than 30%). Targeting CFAEs without linear lesions or PV isolation is associated with a moderate risk (8.3%) of postablation ATs. Following stepwise approaches of catheter ablation incorporating extensive lesions in the LA and RA to terminate persistent AF, ATs can be observed in more than 50% of patients. Although typical AFL should be considered in the differential diagnosis of regular tachycardias (even in the presence of atypical ECG patterns) observed following AF ablation, most of these arrhythmias arise from the LA and can be focal or macroreentrant.¹

LA tachycardias tend to occur at variable time intervals after AF ablation procedures. AT (macroreentrant or focal) can develop during the course of the ablation procedure or up to 1 year after the procedure, but the most common timing appears to be 1 to 2 months after ablation. This time course suggests that healing of ablation lines likely contributes to the substrate for atrial reentry. The occurrence of ATs early after ablation is common and potentially, but not necessarily, predicts later recurrences of both AT and AF. Nevertheless, these tachycardias can be problematic because they frequently are incessant and are associated with rapid ventricular rates, and they are more likely to require electrical cardioversion when compared with the episodes of AF prior to ablation.

Most organized ATs after AF ablation have been shown to be reentrant, and the vast majority are related to gaps in prior ablation lines. Sometimes, confined PV tachycardia in a previously isolated PV can regain ability to propagate into the LA via a gap in the circumferential PV lesion set, resulting in recurrent atrial tachyarrhythmias conducting.²⁵⁴

The three predominant catheter-based techniques for AF ablation appear to be associated with different rates and types of postprocedure ATs. Segmental ostial PV isolation is associated with a lower incidence of atrial tachyarrhythmias (less than 5%). When they do occur, these arrhythmias tend to be focal ATs, often originating from ostial segments of reconnected PVs. Reisolation of the PV and ablation of non-PV foci are usually sufficient to treat this proarrhythmia. LA macroreentry has been reported after segmental PV isolation, but this situation appears to be significantly less common. Most reentrant circuits use the ablated zone as a central obstacle, resulting in perimitral or peri-PV reentry, with the latter more prevalent in patients with larger atria.

Circumferential antral PV isolation has also been complicated by LA tachyarrhythmias, both focal and macroreentrant, and PV-LA conduction recovery is frequently a critical element in these arrhythmias. The area of recovery within an ablated region of the antrum can potentially create a region of slow conduction and the substrate for micro- or macroreentry. When this area is a critical limb of the reentry circuit, reisolation of the PVs by ablation within the antrum terminates the tachycardia. In some cases, it is also possible that the recovered PV conduction allows PV triggers to induce a tachycardia that does not involve the PV antra. These patients also benefit from PV reisolation and elimination of PV triggers. Macroreentrant ATs involving a PV typically involve two gaps in the isolation line; while ablation of one gap can eliminate AT, it is advisable to eliminate the second gap and thereby reisolate the PV. These ATs are less common after PV isolation with cryoballoon compared with RF-based PV isolation.

Wide-area circumferential LA ablation is frequently complicated by LA macroreentrant ATs. Most of those ATs are related to gaps in prior ablation lines, a finding that implies that most postablation ATs are avoidable, either by limiting the amount of linear ablation and/or by confirming complete conduction block across linear lesions. Not infrequently, multiple different tachycardias occur in individual patients. The long linear lesions required in this approach to prevent AF also create new fixed obstacles to propagation, adjacent areas of block, and slow conduction, and eventual discontinuities represent ideal substrates

for large reentrant circuits. Perimitral macroreentrant AT traversing the mitral isthmus is the most common, accounting for approximately 40% of macroreentrant ATs, and macroreentrant circuits traversing the LA roof account for approximately 20%. Less common sites of macroreentry involve the right or left PVs, LA septum, the CTI, and the base of the LAA. Focal ATs also have been reported following circumferential LA ablation, but macroreentrant ATs are much more common. Not infrequently, multiple macroreentrant circuits and multiple-loop reentrant circuits are encountered. In addition, localized reentrant circuits are not uncommon, and they usually arise from the vicinity of the isolated PVs or linear lesions.

Modification of the original circumferential LA ablation technique has involved the addition of linear ablation connecting the superior PVs (roof line) and connecting the left inferior ablation line to the mitral annulus (mitral isthmus line). Whereas some studies demonstrated a reduction in the incidence of postprocedure LA tachycardias, others actually raised concern that the addition of linear lesions, if incomplete, could lead to an increased rather than decreased incidence of this problem. As noted, even when complete conduction block across the linear lesions is achieved, the ablation lines can potentially promote reentry by providing conduction obstacles and protected isthmuses with adjacent anatomic structures in the LA. Therefore these additional ablation lines can actually contribute to, rather than prevent, macroreentry, and further studies are needed to define their role in the ablation strategy.

Importantly, LA macroreentry can be induced in a large percentage (38%) of patients immediately after circumferential LA ablation for AF; however, such inducibility does not seem to predict those patients who subsequently develop clinical episodes of LA tachycardias. Also, the lack of inducibility of such arrhythmias after ablation is not a good predictor of long-term clinical success. Therefore mapping and ablation of LA macroreentry induced during catheter ablation for AF do not seem necessary.

Management of Atrial Tachycardias Following Ablation of Atrial Fibrillation

There is currently no well-defined standard treatment strategy for ATs following AF ablation procedures, and treatment should be tailored to the potential arrhythmia mechanism. It is important to recognize that many of these arrhythmias are self-limited and resolve spontaneously in up to half of patients within the first 3 to 6 months of follow-up. Therefore efforts should be focused at suppressing these arrhythmias with electrical cardioversion and antiarrhythmic medications or controlling the ventricular response with AVN blocking drugs; ablation for LA macroreentrant ATs should be postponed for approximately 3 to 4 months after diagnosis, unless symptoms cannot be controlled. Class III antiarrhythmic agents (dofetilide, sotalol, or amiodarone), together with AVN blockers, are generally preferred for treatment of organized ATs following AF ablation. Class IC antiarrhythmic agents promote slow conduction that can potentially facilitate macroreentrant tachycardias.¹

Understanding the initial lesion set is critical before embarking on AT ablation. For focal ATs following PV isolation procedures, most of the foci are located in a PV or in the antrum of a PV, and reisolation of all reconnected PVs appears to be sufficient in most cases. The septal aspect of ablation lines encircling the right PVs and the area anterior to the left superior PV are particularly vulnerable to recovery of conduction after circumferential PV isolation, thus predisposing patients to the development of LA tachycardia. Particular attention should be paid at these sites to ensure continuous transmural lesions. If the PVs are excluded as the site of origin of a focal AT, mapping then should focus on the other most likely sites of origin, including the posterior LA, mitral annulus, CS, SVC, and crista terminalis. Nonetheless, PV

isolation is still appropriate if there is evidence of PV conduction, even if the focal AT is not arising in the PV, to minimize the possibility of recurrent AF.

Mapping and ablation of LA macroreentry following circumferential LA ablation or circumferential antral PV isolation are frequently challenging. Detailed mapping with a high density of points is necessary to elucidate the mechanism of the arrhythmias, and is discussed in detail in **Chapter 13**. When the macroreentrant circuit can be mapped, ablation lesions should be tailored to interrupt the path of the reentrant circuit. The mitral isthmus, LA roof, and septum account for 75% of the ablation target sites for macroreentrant ATs from the LA. Successful catheter ablation has been reported in approximately 85% of macroreentrant ATs arising in the LA in highly experienced laboratories; however, ablation of macroreentrant ATs occurring in the septal wall is challenging and less successful. Electrical isolation of all reconnected PVs is also appropriate.

Multiple macroreentrant circuits and multiple-loop reentrant circuits are not infrequently encountered after catheter ablation of AF, especially following extensive ablation strategies (**Fig. 15.60**). Transition from one tachycardia to another tachycardia incorporating a different loop of the same circuit or using a different circuit can be encountered during mapping or after successful ablation of the initial tachycardia. In addition, localized reentrant circuits are not uncommon, especially following ablation of longstanding AF. These small circuits usually arise from the vicinity of the isolated PVs or linear ablation lesions.²⁵⁴

Complications of Catheter Ablation of Atrial Fibrillation

Catheter ablation of AF is one of the most complex interventional EP procedures, and the risk associated with such a procedure is higher than for the ablation of most other arrhythmias. Complications include local vascular complications, cardiac perforation, systemic embolism, esophageal injury, PV stenosis, phrenic nerve injury, valvular injury, and proarrhythmia resulting from reentrant tachycardias arising from incomplete ablative lesions.²⁵⁵

Numerous studies have reported major complication rates following catheter ablation for AF ranging from 3.9% to 6.3% and an overall mortality rate of approximately 0.1% to 0.2%. The most frequent causes of mortality were tamponade (25%), atrioesophageal fistula, and (16%)

stroke (16%). There appears a significant association between operator and hospital volume and adverse outcomes.⁵⁵

It is also important to realize that surgical intervention can be life-saving should a severe mechanical complication, such as rupture or massive cardiac perforation or catheter entrapment, occur. Therefore catheter ablation of AF should not be performed, particularly in higher risk patients, if surgical back-up is not readily available.

Pulmonary Vein Stenosis

PV stenosis after AF ablation has been reported with a wide range of incidence, depending on the ablation technique, the operator's experience, and the method for detection of PV stenosis (**see Figs. 32.7 and 32.8**). From 1999 to 2004, reported incidence ranged from 0% to 44% (median 5.4%), whereas later studies reported incidence from 0% to 19% (median 3.1%). Focal ablation and then ostial PV ablation carry the highest risk for PV stenosis. Circumferential antral LA ablation, with ablation limited to atrial tissue outside the PV orifice, seems to have the lowest rates of PV stenosis, whereas the use of an individual encircling lesion set that requires RF ablation between the ipsilateral PVs carries a relatively higher risk. Stenosis seems to be more common in the left-sided PVs. Delivery of energy inside the PV during ablation, although undesirable, is more likely in the left PVs because the ablation catheter moves easily into them when patients breathe.

The prevalence of this complication has decreased because of various factors, including abandonment of in-vein ablation at the site of the AF focus, limiting ablation to the extraostial portion of the PV or PV antrum, use of advanced imaging techniques to define the PV antrum and guide catheter placement, reduction in target ablation temperature and energy output, and increased operator experience. Nonetheless, severe PV stenosis remains an important complication, affecting approximately 1.0% of patients (**see Chapter 32**).

In a recent study of 976 patients who underwent antral PV isolation (from 2005 to 2016) with routine pre- and postablation screening by CMR or CT, mild, moderate, and severe PV stenosis was observed in 31%, 4%, and 1% of patients, respectively. Symptomatic PV stenosis necessitating intervention occurred in only 1 patient (0.1%).²⁵⁶

Although experimental studies have suggested that cryoablation is associated with little or no risk of PV stenosis in humans, PV stenosis has been increasingly reported in clinical studies. In one report of patients undergoing PV isolation using second-generation cryoballoon, mild, moderate, and severe PV stenosis was observed in 31%, 5%, and 1% of the PVs, respectively. The mean reduction of the PV dimension was 18%. A baseline PV ostium, using the smaller 23-mm balloon, and a lower minimum freezing temperature (below -53.5°C) during cryoballoon ablation were associated with a higher risk of PV narrowing. Cryoenergy application sites may be located in a more distal portion of PVs when using the smaller cryoballoon or when the baseline PV ostial size is larger than the largest available cryoballoon. Similarly, significantly low balloon temperatures are potential indicators of a distal cryoballoon location. In addition, supplementation of cryoballoon ablation of the PV with focal ostial RF ablation can be associated with a higher risk of PV stenosis.^{257,258}

Significant PV stenosis (greater than 50% diameter decrease) appears to be exceedingly rare following laser balloon PV isolation, but experience using this technology is limited.^{184,259}

Although PV angiography, electroanatomic mapping, and impedance monitoring have been used to avoid delivery of RF energy to the PV ostia or within the PVs, these techniques are still imperfect. Electroanatomic mapping, for example, relies on the patient's position remaining unchanged throughout the procedure. With patient movement, the 3-D electroanatomic reconstruction of the LA and PVs may not accurately reflect true, contemporaneous anatomy. Similarly, PV

Fig. 15.60 Electroanatomic (CARTO) Mapping of the Macroreentrant Left Atrial (LA) Tachycardias Postablation of Atrial Fibrillation (AF). Activation mapping was performed during two different sustained tachycardias in the same patient with previous wide-area circumferential LA ablation for AF (including LA roof line and mitral isthmus line). The right posterolateral view of the RA is presented. (A) The activation map reveals a figure-of-8 macroreentry circuit at the LA roof that is related to a conduction gap in the previous LA roof ablation line. (B) The activation map demonstrates clockwise perimitral LA macroreentry. LAA, LA appendage; MA, mitral annulus; RSPV, right superior PV.

angiography is typically performed immediately prior to the start of PV ablation. Not only does this provide a crude two-dimensional representation of true PV anatomy, but patient movement later in the procedure can also result in misalignment of the true PV anatomy with that reflected by the PV angiograms. Although impedance monitoring provides online feedback to the location of the ablation catheter relative to the PV, one study found no significant difference in impedance between PV ostial and LA sites. Therefore it is possible for movement of the ablation catheter into the PV ostia to be missed.¹

Atrioesophageal Fistula

Ablation-related esophageal injury is common following AF ablation using RF or cryoenergy. Esophageal mucosal changes consistent with thermal injury are reported in up to 48% of the patients following AF ablation, and clinically silent esophageal ulcerations confirmed by esophagogastroscope or capsule endoscopy can be observed in 10% to 20%. Rarely, esophageal perforation can occur, with or without fistula formation. Fistulas can develop connecting the esophageal lumen to either the LA or pericardium (see Fig. 32.9).^{260–262}

The true incidence of atrioesophageal fistula after RF catheter ablation is unknown, but has been estimated to be between 0.01% and 0.25% post RF ablation and 0.009% to 0.014% following cryoballoon PV isolation, although underreporting is likely. Despite its rarity, atrioesophageal fistula remains a devastating complication associated with high mortality (more than 60%), and accounts for 15.6% of cases with fatal outcome (the second leading cause of death post AF ablation, following cardiac tamponade).^{1,260}

During RF ablation, the risk of esophageal injury likely is enhanced by increasing magnitude and duration of local tissue heating, which is related to catheter tip size, contact pressure, catheter orientation, and energy power output and duration. In addition, ablation strategies incorporating extensive ablation in the LA posterior wall, the type of AF, the use of nasogastric tubes or esophageal temperature probes, and general anesthesia have been associated with an increased rate of esophageal ulcerations. However, the lack of clarity regarding the exact pathophysiology of esophageal injury has hampered efforts to avoid it.

Current approaches to mitigate esophageal injury include the following: (1) assessment of esophageal position before and during ablation (see Fig. 32.11); (2) avoiding ablation in the vicinity of the esophagus; (3) mechanical displacement of the esophagus; (4) monitoring of the esophageal temperature during energy delivery; and (5) reduction of ablation energy power output and duration at sites close to the esophagus. However, no single technique or ablation strategy has been shown so far to unequivocally eliminate or minimize the risk of. Therefore it appears prudent to apply a combination of these preventive techniques during AF ablation. These strategies are discussed in detail in Chapter 32.^{263,264}

Cardiac Tamponade

The risk of intrapericardial bleeding with cardiac tamponade during AF ablation (averaging 1.3%) is higher than that associated with other EP procedures, likely secondary to the common need for two or more transseptal punctures, extensive intracardiac catheter manipulation and ablation, and prolonged high-dose heparinization during the procedure. Cardiac tamponade is the most dramatic complication observed during AF ablation and the leading cause of procedure-related mortality, responsible for 25% of fatalities.²⁶⁵

Several factors can affect the risk of developing cardiac tamponade. High RF power output can increase the risk of cardiac perforation. An audible pop associated with an abrupt rise in impedance is heard in many patients who develop tamponade. Popping occurs because of tissue boiling causing endocardial tissue rupture, and it is increased by

irrigated-tip ablation, high tissue-catheter interface flow, poor or unstable tissue contact, and high catheter tip temperature. Notably, the atrial dome is susceptible to perforation injury during transitioning the catheter tip between the left and right superior PVs. Mechanical perforation can also occur from inadvertent movement of the catheter inside the LAA while it is being positioned during left superior PV or mitral isthmus ablation. Although the use of ICE can potentially limit the risk of cardiac perforation by guiding transseptal puncture and visualizing microbubbles in the LA during RF ablation, it has not eliminated the risk of perforations.

Most perforations occur in the LA. Percutaneous pericardiocentesis effectively restores hemodynamic function in the majority of cases, and up to 16% of cases require surgical closure. Continuation of warfarin through the ablation procedure does not appear to increase the risk of cardiac tamponade. However, patients with therapeutic INR levels who develop cardiac perforation are likely to have a larger amount of blood removed from their pericardium for stabilization and require more blood transfusion units, but the need to undergo emergency surgical exploration is not increased as compared with patients with normal INR levels.²⁶⁶

The occurrence of cardiac perforation is associated with short-term recurrent AF in most patients, in part because the ablation procedure is interrupted by the complication prior to achieving electrical endpoints. Other patients probably have a higher rate of arrhythmia recurrence because of pericardial inflammation, but in most patients this appears to be transient. Most patients with completed ablations have favorable long-term rates of AF elimination, although still lower than expected with uncomplicated cases.

Recent data suggest that the risk of cardiac perforation appears higher in RF catheter ablation as compared to balloon-based PV isolation (cryoballoon and laser balloon). This might be related to the more extensive catheter manipulation required for RF ablation, the safety of which tends to be more dependent on operator and institutional experience.²⁶⁷

Thromboembolism

Systemic thromboembolism is a serious complication of AF ablation, with a reported incidence of 0.1% to 2.8%. In a recent meta-analysis, the rate of stroke was approximately 0.3% and that of transient ischemic attacks was 0.2%. Prior history of stroke or transient ischemic attack is the most potent individual risk factor for cerebrovascular accidents complicating AF ablation; patients with a history of cerebrovascular accidents had a ninefold increased risk of periprocedural stroke. In addition, the incidence of periprocedural stroke increases in a stepwise fashion with an increasing CHA₂DS₂-VASc score.

Thromboembolic events typically occur within 24 hours of the ablation procedure, with the high-risk period extending for the first 2 weeks following ablation. Cerebral thromboembolism is most common, but emboli can also involve the coronary, abdominal, or peripheral vascular circulations.

Importantly, recent studies using diffusion-weighted MRI of the brain have demonstrated a high incidence of acute, asymptomatic cerebral emboli, detected on MRI in up to 50% of patients in the first 24 to 48 hours following AF ablation. The pathogenesis of those lesions remains uncertain, and a majority of the new lesions regress on follow-up MRI. In general, the risk of asymptomatic cerebral emboli associated with AF ablation has been similar between irrigated RF and cryoballoon technologies, but is consistently higher following phased RF multielectrode catheters (PVAC). The long-term prognostic implications of asymptomatic cerebral emboli following AF ablation remain unknown; to date, no clear link has been established between postablation asymptomatic cerebral emboli and long-term cognitive decline.

Therefore, currently, the routine use of brain MRI postablation is not recommended.¹

Potential sources of emboli include thrombus formation on the LA catheters and sheaths, char formation at the tip of the ablation catheter or at the site of ablation, endocardial disruption from the ablation lesions, embolization of air, dislodgment of a preexisting LA thrombus by catheter manipulation, development of thrombi in the LAA after conversion of AF to sinus rhythm, or thrombus formation over the disrupted endothelium. One study correlated new brain MRI lesions with the number of catheter exchanges in and out of LA sheaths.

Careful attention to anticoagulation before, during, and after the ablation procedure is critical to minimize the risk of stroke. TEE should be considered in most patients undergoing AF ablation to screen for LA thrombus. Aggressive intraprocedural anticoagulation is critical, including early heparin administration (preferably before the transseptal puncture), followed by continuous infusion to maintain the ACT above 300 seconds. Also, an uninterrupted perioperative oral anticoagulation strategy (as discussed previously) eliminates a period of inadequate anticoagulation immediately following the ablation procedure and can potentially reduce the risk of thromboembolism.

In addition, meticulous attention to sheath management is paramount to prevent thrombus formation and air embolization, with visualized aspiration and flushing whenever catheters are inserted into the sheaths and continuous flushing of transseptal sheaths with heparinized saline. Open irrigated-tip RF ablation catheters or cryoablation can potentially decrease the formation of char and thrombus at the tip of the ablation catheter. Also, the use of ICE can enable detection of intracardiac thrombi and accelerated bubble formation consistent with endocardial tissue disruption with RF application.

Air Embolism

The most common cause of air embolism is introduction of air into the transseptal sheath. Although air can be introduced through the infusion line, air embolism can also occur with suction when catheters are removed. Careful sheath management, including constant infusion of heparinized saline and air filters, should be observed. Whenever catheters are removed, they need to be withdrawn slowly to minimize suction effects and the fluid column within the sheath should be aspirated simultaneously. The sheath should then be aspirated and irrigated to ascertain that neither air nor blood has collected in the sheath. Particular care is advised when inserting and removing balloon catheters through large sheaths.

Arterial air emboli can distribute to almost any organ, but they have devastating clinical sequelae when they enter the end arteries (see Chapter 32). This situation can lead to the hypoxic manifestations of myocardial injury and cerebrovascular accidents. A common presentation of air embolism during AF ablation is acute inferior ischemia or heart block. This reflects preferential downstream migration of air emboli into the right coronary artery (see eFig. 32.2). Air embolism to the cerebral vasculature can be associated with altered mental status, seizures, and focal neurological signs. The central nervous system dysfunction is attributable to both mechanical obstruction of the arterioles and thrombotic-inflammatory responses of air-injured endothelium (see eFig. 32.3).

Catheter Entrapment in the Mitral Valve Apparatus

There are several reports of the ring catheter becoming entrapped in the mitral valve apparatus during AF ablation, resulting in valve injury that required thoracic surgery and valve replacement. The risk of this complication can be minimized by preventing anterior displacement of the ring catheter during the ablation. Catheter position can be monitored by using a combination of orthogonal fluoroscopy (ensuring that

the ring catheter remains behind the CS on the RAO view) and ICE, as well as by paying close attention to the characteristics of the electrograms recorded on the catheter.

Catheters entangled in the valve apparatus can be difficult to free by clockwise and counterclockwise rotation of the shaft, especially after significant tugging has occurred. To prevent this, prior to pulling on the catheter, one may consider advancing the catheter toward the LV apex. Advancing the sheath over the catheter may facilitate the effort further and is also recommended so that the catheter can be withdrawn into the sheath and the whole assembly withdrawn to the LA.

Forcible traction of the catheter can potentially damage the valve and ultimately necessitate mitral valve replacement. Therefore when gentle manipulation and moderate traction are unsuccessful, removing the catheter by thoracic surgery should be considered.

Phrenic Nerve Injury

Phrenic nerve injury has been reported following AF ablation using RF, cryotherapy, laser, and ultrasound energy. In addition, phrenic nerve injury occurs independently of the strategy of AF ablation used (PV isolation vs. wide-area circumferential LA ablation). Complete or partial recovery of diaphragmatic function is observed in most patients (more than 80%), but can take several months.

Right phrenic nerve injury can be observed after RF electrical isolation of the right-sided (mostly superior) PV (up to 0.48%) or isolation of the SVC (2.1%). The incidence of right phrenic nerve injury is significantly higher in the setting of cryoballoon PV isolation, occurring in more than 11% with the first-generation cryoballoon. Using the second-generation cryoballoon, transient (intraprocedural only) and persistent right phrenic nerve injury has been observed in 9.0% and 3.0% of patients, respectively. Rarely, left phrenic nerve injury can occur during endocardial ablation AF or AT in the region of the proximal roof of the LAA and ablation within the distal CS.^{175,176}

Studies indicated that transient phrenic nerve injury occurs early and uniformly before permanent injury. Therefore when ablation is performed in areas at high risk of phrenic nerve injury (inferoanterior part of right PV ostium, posteroseptal part of the SVC, and proximal LAA roof), monitoring of phrenic nerve function is necessary to prevent permanent damage. This approach entails continuous pacing of the phrenic nerve (using a catheter positioned in the SVC at a site superior to the ablation target site) during energy application, with simultaneous monitoring ipsilateral diaphragmatic contractility (by palpation, fluoroscopy, ICE, or diaphragmatic electromyography) (see Fig. 32.6). Early recognition of impending phrenic nerve injury during energy delivery allows immediate interruption of the energy delivery prior to the onset of permanent injury, which is associated with the rapid recovery of phrenic nerve function.^{1,177}

When the procedure is performed under general anesthesia, it is important to avoid paralytic agents or use short-acting paralytic agents only at the time intubation and allow sufficient time for the paralytic effect to fade away before ablation or use a reversal agent (e.g., neostigmine).^{175,176,268}

Peri-Esophageal Vagal Nerve Injury

The right and left vagal nerves descend alongside the esophagus into the abdomen and innervate most of the upper gastrointestinal system and control esophageal peristalsis, the esophageal and pyloric sphincters, and gastric motility. In the posterior mediastinum, the right and left vagal trunks form a plexus anteriorly (34%), posteriorly (19%), or both anteriorly and posteriorly (44%) around the lower portion of the esophagus. Anterior esophageal plexus lies in close proximity to the LA posterior wall, rendering it susceptible to thermal injury during RF and cryoballoon LA ablation.

Clinically manifest gastroparesis appears to occur more commonly with cryoballoon ablation as compared with RF ablation of AF (10% vs. 6% in one report), but is more likely to be reversible. During cryoablation, lower temperatures during ablation of the inferior PVs and small LA size are associated with increased risk of gastroparesis.

Silent upper gastrointestinal functional abnormalities after AF ablation, as detected by functional studies (esophageal manometry and gastric emptying studies), are common, occurring in up to 74% of the patients. Typically, these abnormalities are transient and resolve within 3 to 6 months.^{269,270}

Peri-esophageal vagal nerve injury typically manifests with symptoms related to gastroparesis and delayed gastric emptying, including epigastric discomfort, abdominal pain, nausea, vomiting, and bloating. Symptoms often develop within a few hours to a few days after the ablation procedure. The duration and severity of symptoms can vary widely, but the vast majority of patients eventually recover almost completely with conservative treatment.^{271,272}

Patients are diagnosed with peri-esophageal vagal nerve injury if they exhibit symptoms of delayed gastric emptying and if the findings of gastrointestinal fluoroscopy, endoscopy, or CT reveal the presence of a medium to large amount of food residue even after overnight fasting, indicating gastric hypomotility. Other methods to evaluate gastric motility include scintigraphy using isotope-labeled solid food or real-time MRI.²⁷³

Significantly symptomatic patients are managed with fasting and then gradual introduction of small, low-fat, and low-fiber meals. Erythromycin, mosapride, and metoclopramide can be of value in stimulating gastric motility.

Stiff Left Atrial Syndrome

The stiff LA syndrome refers to extensive atrial scarring secondary to RF ablation, which can lead to reduced LA compliance. The impaired LA diastolic dysfunction can cause increased LA pressure and pulmonary hypertension, and precipitate right heart failure. Preoperative risk factors include LA scar, small LA diameter (less than 45 mm), elevated mean LA pressure, diabetes, and sleep apnea syndrome.²⁷⁴

The incidence of stiff LA syndrome after RF ablation is estimated at 1.4% to 8%. However, it is possible that this complication remains under-recognized because of mild or nonspecific symptoms that could be attributed to other comorbidities (e.g., recurrent atrial arrhythmias or sleep apnea).²⁷⁴

Stiff LA syndrome typically presents with symptoms of right heart failure associated with pulmonary hypertension and elevated LA pressure (with large V waves recorded on pulmonary capillary wedge pressure or LA pressure tracings), in the absence of significant LV dysfunction, mitral regurgitation, or PV stenosis. The diagnosis requires a high index of suspicion and relies on clinical symptoms, measurement of LA pressure, and the determination of pulmonary arterial pressure. Diuretics are the main therapeutic intervention. Sildenafil may be considered in refractory cases.^{274–276}

Sinus Bradycardia Due to Sinoatrial Artery Damage

The sinus node artery arises from the circumflex coronary artery in about 40% of patients and courses over the roof of the LA. In this location, it is vulnerable to damage by roof line ablation (connecting contralateral PV antral isolation lines). Damage is suspected when extreme sinus bradycardia, that had not been present prior to ablation, is observed immediately after ablation and in the absence of ablation in the high lateral RA that could affect sinus node function. Despite the frequency of extensive ablation on the LA roof, this complication is quite rare (less than 1% of patients); permanent pacing is necessary in a significant proportion due to persistence of unacceptably slow sinus rates.

Pericarditis

Mild, self-limited pericarditis, manifesting as pleuritic chest pain, is very common in the early postoperative period, and is likely related to epicardial inflammation resulting from transmural ablation lesions. However, a more severe form of ablation-induced pericarditis can develop in 0.1% and 0.6% of patients, which can manifest several days or weeks postablation, and can result in delayed pericardial effusion and cardiac tamponade. In addition, acute pericarditis likely underlies some of the early recurrences of atrial tachyarrhythmias postablation. There is currently no evidence to support the use of nonsteroidal antiinflammatory drugs or steroids to prevent AF recurrences.¹

RECOMMENDATIONS AND CONTROVERSIES

Determination of the Necessity of Pulmonary Vein Electrical Isolation

Although durable PV electrical isolation increases the likelihood of procedural success, several studies have found that the relationship between durable PV isolation and freedom from AF was modest, and was a significant overlap between AF recurrence and status of PV electrical conduction; electrical reconnection in at least one PV occurred in 86% of patients with AF recurrence and in 59% patients who were AF-free during follow-up.

In addition, strategies without complete PV isolation or non-PV foci-targeted, such as ablation of atrial ganglionated plexuses, focal impulse and rotor ablation, CFAE ablation, and linear catheter ablation without PV isolation, have also been reported to be effective in AF treatment, suggesting multiple mechanisms involved.²⁷⁷

Nonetheless, PV electrical isolation is widely accepted as an objective, standard, and generalizable endpoint and is currently considered central to any AF catheter ablation strategy, and most centers performing AF ablation are empirically isolating all four PVs, without mapping or specific targeting of the trigger of the focus causing the arrhythmia. Furthermore, ablation is preferably performed outside the tubular portion of the PV (i.e., antral ablation as opposed to ostial ablation) to avoid the risk of PV stenosis and improve the efficacy of the procedure. The antrum blends into the posterior wall of the LA, and, on the posterior wall, there is little space between adjacent antra. Therefore to encompass as much of the PV structure as possible, ablation needs to be performed around the entire antrum, along the posterior LA wall. Although different groups may refer to ablation in this region by different names, such as wide-area LA ablation, circumferential antral PV ablation, or extraostial isolation, the lesion sets produced by the procedures are all similar. There is less consensus, however, on the distance from the PV ostia at which the optimal circumferential lesions should be placed. The greater the distance is, the greater the number of applications and density of lesions will be required to achieve isolation, but the lower the likelihood of PV stenosis. Furthermore, the greater the distance is from the ostia, the larger will be the area encircled and the greater the potential impact of the lesion set on atrial rotors and sites within the posterior LA, which can potentially contribute to the maintenance of AF. However, it is clear that wide-area circumferential LA ablation minimizes the risk of PV stenosis, but at the cost of a higher incidence of macroreentrant ATs and more extensive LA ablation with possible deleterious hemodynamic effects.^{1,10}

Determination of the Necessity of Adjunctive Substrate Modification

While elimination of PV triggers appears to be an adequate initial ablation strategy for patients with paroxysmal AF, atrial substrate modification takes on a more important role in the setting of persistent AF. However, current techniques of substrate modification are technically

challenging and lack adequate procedural endpoints to determine when enough ablation has been performed to modify the atrial substrate sufficiently. In addition, these approaches involve more extensive ablation that can potentially increase the risk of complications, impair LA mechanical function, and predispose to the development of LA macroreentry. Therefore to balance efficacy and safety, it is not recommended to use such an approach for all patients. A rational approach that targets a particular patient profile, rather than a unified strategy used for all patients, may be advisable.

For paroxysmal AF, circumferential antral electrical isolation of all PVs is the procedure of choice. If a focal trigger is identified outside the PVs, it should be targeted if possible. The clinical value of adjunctive substrate-based techniques has not been definitively proven, and these approaches are likely unnecessary, especially during the initial ablation procedure.

The optimal ablation strategy in patients with persistent and longstanding persistent AF remains controversial. Currently, circumferential antral isolation of all PVs is recommended as the cornerstone of most ablation procedures in patients with nonparoxysmal AF. In addition to elimination of the most common AF triggers, this technique incorporates substrate modification by considerable debulking of the atrium as well as elimination of CFAEs, rotors, and ganglionated plexuses commonly located within the circumferential ablation lesions around the PV antra.

However, an ablation strategy limited primarily to antral PV isolation is associated with lower long-term AF-free survival rates in patients with nonparoxysmal AF than those with paroxysmal AF, suggesting that modification of AF substrate outside the PVs appears to be necessary in selected patients. In fact, many observational studies demonstrated that adjunctive substrate-based ablation techniques could improve ablation efficacy. Some substrate-based strategies involve empirical ablation of presumably arrhythmogenic atrial substrate, including linear LA ablation (LA roof and mitral isthmus lines, and LA posterior wall isolation), CFAE ablation, PV denervation, and empiric isolation of extra-PV structures without demonstration of their role as triggering foci in an individual patient. More recently, individualized ablation strategies have been proposed, whereby patient-specific arrhythmogenic atrial substrate is identified and targeted for ablation. Those strategies include voltage-guided substrate modification and focal impulse and rotor ablation.

Accordingly, supplementary linear LA ablation, CFAE ablation, or rotor ablation was recommended by many investigators, especially in patients with longstanding persistent AF or during redo ablation after failure of an initial PV-based ablation procedure.²⁷⁸

Other investigators recommended stepwise or tailored approaches of increasing ablation lesions until persistent AF is terminated by ablation or until AF is rendered noninducible by rapid atrial pacing or infusion of isoproterenol or adenosine. A common approach involved starting with circumferential antral PV isolation, which is then followed by linear ablation across the LA roof, CS isolation, ablation of CFAEs, mitral isthmus ablation, and SVC isolation in a stepwise fashion whereby each step is started if AF still persists after completion of earlier steps. It should be noted, however, that despite the best efforts with various combinations of several ablation strategies, converting chronic AF to NSR solely by ablation may not occur in most patients. Hence, an endpoint of acute termination of chronic AF may not be practical. Moreover, whether acute termination of chronic AF by RF ablation is a predictor of long-term clinical efficacy remains to be proven.^{219,220}

Of note, substrate-based ablation techniques are typically used in conjunction with PV isolation. Their use as a stand-alone procedure for either paroxysmal or persistent AF without any attempt to isolate the PVs electrically has been associated with high rates of recurrence, and this approach has been abandoned by many centers.¹⁴⁶

Importantly, at present, no strategy is proven to improve outcomes for AF ablation beyond antral PV isolation. Recent randomized trials and meta-analyses have suggested that the commonly applied ablation sets beyond PV isolation provide inconsistent benefit. The Substrate and Trigger Ablation for Reduction of Atrial Fibrillation Part II (STAR-AF II) and the Catheter Ablation of Persistent Atrial Fibrillation (CHASE AF) randomized studies demonstrated that the success of PV isolation was not improved by the empirical uniform or stepwise (aimed at AF termination) application of extensive adjuvant ablation (LA linear lesions or CFAE ablation) after either a single or multiple ablation procedures.^{146,219,220,249,279}

Therefore until better evidence of the benefit of extra-PV ablation is available, circumferential antral PV isolation alone appears reasonable, though often inadequate in itself, at least in an initial ablation procedure for patients with paroxysmal and nonparoxysmal AF. Even for patients undergoing redo ablation for AF, an initial strategy of PV reisolation appears reasonable.

Nonetheless, it is important to recognize that while it is true that current substrate-based ablation strategies have not improved that outcome, the efficacy of PV isolation alone remains suboptimal, especially in nonparoxysmal AF. Therefore improved understanding of the underlying mechanisms of AF is necessary to enable the identification and targeting the arrhythmogenic substrate.²⁸⁰

It remains unclear why adjunctive ablation strategies have not improved overall arrhythmia-free outcome. It may be that they are helpful in some patients but not all, or helpful in some but harmful in others, negating any signal of benefit in large trials. It is also possible that, just as in the case of PV isolation, where the strategy seems to be of benefit but its execution is imperfect (with recurrent PV-LA conduction associated with AF recurrence), the theory behind adjunctive ablation strategies is sound, but they are imperfectly performed leading to no net benefit.

According to the 2017 HRS/EHRA/ECAS/APHRS/SOLAECE expert consensus statement, electrical isolation of all PVs is recommended during all AF ablation procedures, as is concomitant ablation of the CTI in patients with clinical or inducible typical AFL. Also, if a reproducible focal trigger that initiates AF is identified outside the PV ostia at the time of an AF ablation procedure, ablation of the focal trigger should be considered. Posterior wall isolation might be considered for initial or repeat ablation of persistent or longstanding persistent AF. If linear ablation lesions are applied, completeness of conduction block across the ablation line should be verified. The usefulness of other substrate-based mapping and ablation approaches (including linear ablation of various sites, ablation of ganglionated plexuses, CFAE ablation, FIRM, and voltage-guided ablation) as an initial or repeat ablation strategy for persistent or longstanding persistent AF is not well established.¹

ATRIOVENTRICULAR JUNCTION ABLATION

Rationale

AV junction ablation and permanent pacemaker implantation (the “ablate and pace” strategy) are often considered as a last resort treatment, reserved mainly for patients with highly symptomatic AF with rapid ventricular rates when both rhythm control and medical rate control strategies have failed or were poorly tolerated, especially those with tachycardia-induced cardiomyopathy.

In addition, in patients with advanced heart failure requiring cardiac resynchronization therapy that continue to have a high burden of AF despite a rhythm control approach, AV junction ablation can potentially improve long-term survival, NYHA class, and LV systolic function. In order to achieve the benefit of cardiac resynchronization therapy, it must

be operating at or near 100% of the time. This level can be difficult to achieve in AF patients; even though the ventricular rate during AF can be “well controlled” with medical therapy, ventricular rates often exceed the lower rate limit of the pacemaker. In these patients, AV junction ablation ensures a high percentage of biventricular pacing without fusion from AF impulses conducted through the AVN and attenuates cardiac output impairment resulting from R-R interval variability. AV junction ablation also can be of value in ICD recipients in whom rapid ventricular rates during AF trigger inappropriate ICD shocks.⁴

The pacemaker can be single-chamber (VVI) for permanent AF, dual-chamber (DDD) for paroxysmal or recurrent persistent AF, or biventricular for patients with LV systolic dysfunction. Also, direct HB pacing (with the pacing electrode positioned in the membranous septum) or para-Hisian pacing can enable physiological pacing in patients without distal conduction disease by recruiting the native HPS, thus avoiding electrical dyssynchrony and potentially preventing pacing-induced cardiomyopathy and heart failure (see Chapter 9).

Ablation of the AV junction is successful in almost 100% of cases, and late recovery of AV conduction is rare. However, this procedure still mandates anticoagulation, possibly requires antiarrhythmic therapy to control nonpermanent AF, and commits the patient to life-long pacing therapy.^{281,282}

The timing of AV junction ablation in relation to pacing is debatable, mainly in the setting of paroxysmal AF. In most EP laboratories, permanent pacemaker implantation is performed prior to the ablation procedure. Long-term pacemaker function does not seem to be affected by RF ablation; however, the pacemaker may develop a transient unpredictable response during RF application in up to 50% of patients, including inhibition, switching to back-up mode, oversensing, undersensing, loss of capture, exit block, and electromechanical interference. These responses argue for the use of an external pacemaker during the ablation procedure. In patients with paroxysmal AF, a dual-chamber pacemaker may be implanted first, and the need for AV junction ablation is reassessed after 1 to 3 months of intensification of medical therapy (i.e., AVN blocking drugs).

Target of Ablation

The ablation target site of this approach is located closer to the compact AVN than the HB in the anterosuperior region of the triangle of Koch. This approach selectively ablates the AVN, and not the HB. This ensures ablation of the proximal part of the AV junction to preserve underlying automatism and to avoid complete pacemaker dependency. Occasionally, when ablation of the AVN is unsuccessful, RF ablation of the HB may be performed using a right- or left-sided approach.

Ablation Technique

A 4- or 8-mm-tip ablation catheter is initially positioned at the AV junction to obtain the maximal amplitude of the bipolar His potential recorded from the distal pair of the electrodes. The catheter is then withdrawn while using consistent clockwise torque on the catheter to maintain septal contact until the His potential becomes small or barely visible, or disappears while recording a relatively large atrial electrogram (A/V ratio greater than 1) or, in patients with AF, until the His potential disappears under the fibrillatory waves (Fig. 15.61). The presence of His and atrial signal on the distal bipole of the ablation catheter, together with an absence of ventricular signal on the proximal bipole, significantly improves the odds of successful AVN ablation without new-onset RBBB.²⁸³

An alternative approach is to position a quadripolar catheter at the HB position. The tip of the ablation catheter is then withdrawn to approximately 2 cm below and to the left of the tip of the HB catheter in the RAO view (Fig. 15.62). Occasionally, in 5% to 15% of patients,

Fig. 15.61 Optimal Ablation Site for Atrioventricular Junction Ablation During Normal Sinus Rhythm. The distal ablation electrodes (ABL_{dist}) record a small His potential and a large atrial electrogram (atrial-ventricular ratio greater than 1). More prominent His potentials, such as recorded by the proximal or distal His bundle catheter bipoles, suggest inappropriate site for ablation. His_{dist} , Distal His bundle; His_{prox} , proximal His bundle.

when the right-sided approach is undesirable or unsuccessful, a left-sided approach to ablate the HB may be used. The ablation catheter is advanced retrogradely through the aorta into the LV, withdrawn so that the catheter tip lies against the membranous septum just below the aortic valve, and records a large HB electrogram and small atrial electrogram (Fig. 15.63). Often, no atrial electrogram is seen. A large atrial electrogram suggests that the catheter tip is close to the LA above the aortic valve; ablation should not be attempted at this site. The left-sided approach typically requires fewer RF applications than the right-sided approach.

Several reports described the feasibility of catheter ablation of the AV junction performed via the SVC during concurrent implantation of a pacemaker or defibrillator. Implantation of the RV lead is performed first, followed by ablation of the AV junction. In patients undergoing device upgrade, in whom the old RV lead is to be utilized for the new device system, AV junction ablation is performed before implantation of the other (atrial and/or CS) leads. Once satisfactory pacing and sensing function of the RV lead is verified, this lead is connected to a temporary pacemaker programmed to the VVI mode at a pacing rate of 30 per minute to provide back-up pacing during and after ablation of the AV junction. Subsequently, the ablation catheter is introduced through the subclavian vein into the RV and is positioned near the HB region by deflection of the tip superiorly to form a J shape; the catheter is then withdrawn so that it lies across the superior margin of the tricuspid annulus (Fig. 15.64). Alternatively, the catheter can be looped in the RA (figure-of-6) and the body of the loop advanced in the RV so that the tip of the catheter is pointing toward the RA and lying on the septal aspect of the RA. Gentle withdrawal of the catheter can increase the size of the loop and allow the catheter tip to rest on the HB location (see Fig. 15.64). From that location, fine manipulation of

Fig. 15.62 Right-Sided Approach to Ablation of the Atrioventricular Junction. Fluoroscopic (right anterior oblique [RAO] and left anterior oblique [LAO]) views of the ablation catheter position (Abl) in relation to the His bundle (HB) catheter at the optimal site of atrioventricular junction ablation. The distal ablation electrode is positioned just proximal and inferior to the proximal HB electrodes.

Fig. 15.63 Left-Sided Approach to Ablation of the Atrioventricular Junction. Fluoroscopic (right anterior oblique [RAO] and left anterior oblique [LAO]) views of the ablation catheter introduced via a transaortic approach in relation to the His bundle (HB) catheter at the optimal site for atrioventricular junction ablation (Abl). The distal ablation electrode is positioned just below the aortic cusp in the left ventricular outflow region, opposite the HB catheter in the right ventricle.

the tip of the catheter is performed to bring to the region of the compact AVN in the anterosuperior aspect of the triangle of Koch (a location proximal and inferior to the HB region). Clockwise rotation of the catheter is essential to maintain adequate contact with the septal aspect of the RA. Once successful ablation AV junction is achieved, the ablation catheter is withdrawn, and the atrial lead (or CS lead in patients undergoing biventricular device implantation) is implanted via the same introducer sheath used for ablation.²⁸⁴

RF energy is delivered with a power output of 50 W, targeting a temperature of 60°C to 70°C, and for a duration of 30 to 120 seconds. AV block may appear immediately or after several RF applications. Typically, at good ablation sites, an accelerated junctional rhythm is induced during RF application (Fig. 15.65).

Endpoints of Ablation

The endpoint of ablation is achieving complete AV block. It is preferable to achieve AVN block with a slow, stable junctional escape rhythm

to avoid total pacemaker dependency; however, sometimes this is difficult to achieve, and HB ablation with fascicular or no escape rhythm is the end result (see Fig. 15.65).

Outcome

Complete AV block is successfully achieved by a right-sided ablation approach in 93% to 97% of patients. Achieving complete AVN block specifically, however, is less successful (80% to 90%). Ablation of the AV junction can be difficult to achieve in patients with atrial enlargement or hypertrophy, and in the presence of moderate-to-severe tricuspid regurgitation. Overall, the recurrence of AV conduction after an acutely successful AV junction ablation is approximately 4% to 5%.^{285,286}

Most patients who undergo RF ablation of the AV junction are pacemaker dependent after the procedure, as defined by lack of an escape rhythm that is faster than 40 beats/min. Following AV junction ablation, an escape rhythm develops in 70% to 100% of cases, and the absence of escape rhythm immediately after ablation seems to be the

Fig. 15.64 Ablation of the Atrioventricular Junction via the Superior Vena Caval Approach. Fluoroscopic (right anterior oblique) views of the ablation (*Abl*) catheter introduced via the left axillary vein. Implantation of the pacemaker ventricular lead is initially performed. A transcatheter aortic valve prosthesis is also seen. The ablation catheter is positioned near the His bundle region by deflection of the tip superiorly to form a J shape and then withdrawing the catheter so that it lies across the superior margin of the tricuspid annulus (A), or by looping the catheter in the right atrium (RA; figure-of-6) and then advancing the body of the loop into the right ventricle (RV) so that the tip of the catheter is pointing toward the RA and lying on the septal aspect of the RA (B).

Fig. 15.65 Atrioventricular (AV) Junction Ablation (*ABL*) During Atrial Fibrillation (*AF*). A ventricular pacemaker was implanted prior to ablation and programmed to VVI pacing mode at 30 beats/min. Radiofrequency (*RF*) application results in complete AV block with an escape ventricular paced complex (*blue arrow*) followed by the emergence of a junctional escape rhythm at 35 beats/min.

only predictor for long-term pacemaker dependency. Although the appearance of an escape rhythm does not obviate the need for pacing, it may provide reassurance in case of pacemaker failure.

Malignant ventricular arrhythmias and SCD have been observed in the early phase following AV junction ablation. Polymorphic VTs are related to electrical instability caused by an initial prolongation and then slow adaptation of repolarization caused by changes in the heart rate and ventricular activation sequence. Most polymorphic VTs, torsades de pointes, and VF that have been reported seem to be consistent with a pause- or bradycardia-dependent mechanism. Anomalous dynamics of the paced QT intervals have been observed until the second day after AV junction ablation in patients with chronically rapid ventricular rates during persistent AF, resulting in prolongation of the QT interval when the (paced) heart rate is less than 75 beats/min. This finding may explain the ventricular arrhythmias occurring after AV junction ablation and

may also explain the beneficial effects of temporary pacing at relatively fast rates. On the other hand, bradycardia may not be the sole factor. Sympathetic tone augmentation following AV junction ablation has been described in patients paced at 60 beats/min, thus causing prolongation of the action potential duration and RV refractoriness, whereas sympathetic tone was reduced in patients paced at 90 beats/min. Such an increase in sympathetic activity and prolongation in action potential duration can potentially promote early after-depolarization and triggered activity, which can mediate torsades de pointes and polymorphic VT. To reduce the risk of these arrhythmias, routine pacing at 80 beats/min has been recommended following AV junction ablation. Patients with high-risk factors for arrhythmias, such as congestive heart failure or impaired LV function, may require pacing at higher rates (e.g., at 90 beats/min for 1 to 3 months) as well as in-hospital monitoring for at least 48 hours. Adjustment of the pacing rate, although rarely to less

than 70 beats/min, is usually undertaken after 1 week in most patients, preferably after an ECG evaluation for repolarization abnormalities at the lower rate.²⁸⁶

Another adverse effect of the ablate and pace approach is ventricular dyssynchrony induced by RV pacing, which can lead to impairment of LV systolic function. Positioning the ventricular pacing electrode in the RV septum, HB pacing, and biventricular pacing are being evaluated to reduce the impact of this potential problem.

ATRIOVENTRICULAR NODAL MODIFICATION

Rationale

AVN modification is performed to injure the AVN to reduce the ventricular rate during AF without producing complete heart block. AVN slow pathway ablation has been observed to increase the refractory period of the fast pathway, rendering it incapable of as rapid AV conduction as had been present before slow pathway ablation. As compared with ablation of the AV junction, AVN modification has the advantage in that it results in adequate control of the ventricular rate in most

patients while obviating the need for a permanent pacemaker. Therefore it may be appropriate to attempt first to modify AV conduction in patients with AF and rapid ventricular rates who are appropriate candidates for ablation of the AV junction. Because the risk of inadvertent complete AV block is approximately 20%, the use of the procedure should be limited at present to patients with AF who are symptomatic enough for ablation of the AV junction and implantation of a permanent pacemaker to be justified.

Target of Ablation

The right posteroseptal area along the tricuspid annulus extending from the CS os to the recording site of the HB can be divided into three regions: posterior, medial, and anterior. The conventional technique for ablation of the AV junction uses sites located anteriorly and superiorly on the tricuspid annulus. In contrast, with the technique used to modify AV conduction, the target sites are located inferiorly and posteriorly near the tricuspid annulus close to the CS os (i.e., in the posterior or midatrial septum) (Fig. 15.66). In the presence of dual AVN physiology, the slow AVN pathway is targeted, as described for ablation of AVNRT.

Fig. 15.66 Atrioventricular Node (AVN) Modification During Atrial Fibrillation (AF). *Upper panel*, Fluoroscopic (right anterior oblique [RAO] and left anterior oblique [LAO]) views of the ablation catheter position (Abl) in relation to the His bundle catheter at the optimal site of AVN modification. The distal ablation electrode is positioned in the posteroatrial or midatrial septum near the tricuspid annulus, close to the coronary sinus ostium. *Lower panel*, AF with rapid ventricular response is initially observed (*at left*). Radiofrequency (RF) application results in slowing of the ventricular rate (*at right*) but not complete AV block, as indicated by irregularity of the rhythm.

Ablation Technique

Two quadripolar-electrode catheters are inserted into a femoral vein and positioned at the HB and in the RV. An ablation catheter with a 4-mm tip is used. In patients with no demonstrable dual AVN physiology, RF energy is delivered during AF with continuous infusion of isoproterenol (4 µg/min) to permit immediate assessment of the effect of each RF application. The ventricular rate during AF, obtained after administration of isoproterenol, is presumed to simulate the maximal rate of clinical AF. If NSR is present, AF is induced by rapid atrial pacing before the delivery of RF energy. The ablation catheter is initially positioned against the posterior RA septum, at the level of or lower than the CS os, to record a stable electrogram for at least 10 seconds, with a maximal A/V electrogram amplitude ratio of 0.5 or lower.

RF energy is delivered for 20 seconds at 30 W. If there is no change in the ventricular rate or no accelerating junctional rhythm within 20 seconds, higher energy (an increment of 5 W every 20 seconds, up to 40 W) is delivered to the same site. Whenever there is an abrupt lengthening of the R-R interval or appearance of an accelerated junctional rhythm, the application of energy is immediately discontinued (see Fig. 15.66). If the ventricular rate is still higher than the endpoint ventricular rate (i.e., more than 130 beats/min), higher energy output is delivered to the effective site, or the ablation site is changed and the catheter is repositioned in progressively upward (more superior and anterior) positions along the tricuspid annulus until the endpoint is achieved. RF energy should not be delivered at the upper third of the atrial septum, where an HB potential is visible.

If the endpoint ventricular rate could not be achieved after RF application to the posterior and mid-atrial septum, a decision should be made about whether to attempt complete ablation of AVN. In the presence of dual AVN physiology, RF energy is delivered during NSR to eliminate a slow AVN pathway. The ablation technique is similar to that described for ablation of AVNRT.

Endpoints of Ablation

The endpoint of the procedure is an average ventricular rate of 120 to 130 beats/min or 70% to 75% of the maximum preablation ventricular rate during infusion of isoproterenol (4 µg/min).

Outcome

Short-Term Results

The immediate success of AVN modification to control the ventricular rate without inducing pathological AV block is approximately 75% to 92%.

Long-Term Results

In one report, 92% of patients with paroxysmal AF and uncontrolled ventricular rates refractory to antiarrhythmic drugs achieved adequate slowing of the ventricular rate and were free of symptoms without any antiarrhythmic drug or the need for a permanent pacemaker. The mean resting, ambulatory, and minimal ventricular rates during AF usually remained stable during an interval from 2 days to 3 months after the modification procedure. However, the mean maximal ventricular rate tended to increase (by up to 25%) during this period, which may reflect partial recovery of AV conduction from the immediate effects of RF energy. Nevertheless, the mean maximal ventricular rate during exercise or isoproterenol infusion at 3 months of follow-up remained approximately 25% lower than at baseline, a degree of attenuation adequate to result in the persistent resolution of symptoms.

Atrioventricular Block

Inadvertent complete AV block that necessitates implantation of a permanent pacemaker occurs in approximately 20% to 25% of patients. Of those patients who develop transient AV block during RF application, approximately two-thirds develop persistent AV block within the first 36 to 72 hours after the procedure. It may be that transient thermal injury to the AV conduction system results in an inflammatory reaction responsible for the delayed occurrence of permanent injury. Regardless of the mechanism, if transient AV block occurs during an attempt to modify AV conduction, continuous ECG monitoring on an inpatient basis is appropriate for 3 to 4 days to watch for a recurrence of AV block.

Limitations

The AVN modification approach has several disadvantages, including subsequent development of inadvertent complete AV block, as well as failure to maintain adequate long-term rate control. Also, AVN modification is applicable only to patients who do not have symptoms caused by irregular heart rhythm. An irregular, conducted rhythm can be hemodynamically less efficient than a regular paced rhythm. Therefore AVN modification without pacemaker implantation has fallen out of favor and is now rarely performed.

PERCUTANEOUS LEFT ATRIAL APPENDAGE DEVICE CLOSURE

Percutaneous device closure of the LAA has emerged as a promising alternative therapeutic approach for stroke reduction in selected patients with nonvalvular AF. The Watchman LAA occlusion device has the largest body of clinical randomized and nonrandomized data that has shown the safety and efficacy of this device as an alternative to warfarin for thromboembolic prophylaxis in patients with nonvalvular AF. Other devices such as the Amplatzer Cardiac Plug (St. Jude Medical), WaveCrest LAA occluder (Coherex Medical, Salt Lake City, UT, United States), and the LAmbré LAA occluder (Lifetech Scientific Corp, Shenzhen, China), have not been tested in randomized controlled trials, and the data regarding the safety and efficacy of these devices are limited. The Amplatzer Cardiac Plug is approved in Europe but not the United States.

The Watchman device is approved as an alternative to warfarin for stroke prevention in the United States and Europe. In the United States, the Watchman device is approved as an alternative to warfarin for stroke prevention in patients with nonvalvular AF who: (1) are at increased risk of stroke and systemic embolism on the basis of CHADS₂ or CHA₂DS₂-VASc scores; (2) deemed by their physicians to be suitable for warfarin therapy; and (3) have an appropriate rationale to seek a nonpharmacological alternative to warfarin, taking into account the safety and efficacy of the device compared with warfarin. Exclusion criteria include contraindications to warfarin, any comorbidity requiring ongoing warfarin, or preexisting LA thrombus.¹²²

The safety of the Watchman in patients who are poor candidates for even short-term anticoagulant or antiplatelet therapy is currently unknown. In the United States, patients with an absolute contraindication to oral anticoagulation therapy are presently not considered candidates for the Watchman device. However, recent studies suggest that a history of spontaneous major bleeding might not be an absolute contraindication for short-term oral anticoagulation therapy that is required after Watchman device implantation. Nonetheless, it is important to note that inadequate LAA closure by the Watchman device can potentially be thrombogenic; even with continued anticoagulation, the risk for thromboembolism in these patients can be higher than without

the Watchman device. This risk should be carefully considered given the fact that the majority of patients referred for LAA occlusion have poor tolerance to long-term oral anticoagulation.

Left Atrial Appendage Anatomy

The LAA is the only cardiac structure in the LA derived from the primitive atrium; the main LA is formed from the outgrowth of the PVs. The LAA interior surface is formed by a smooth endocardial surface and pectinate muscles that form ridges (trabeculations) and cavities. Despite the heavily trabeculated endocardium, the LAA wall is remarkably thin (approximately 1 mm). The LAA lies anteriorly in the AV sulcus in close proximity to the left circumflex artery, the great cardiac vein, the left phrenic nerve, and the left PVs. The tip of the LAA can be in a variety of positions, lying over the pulmonary trunk and the left anterior descending coronary artery, pointing posteriorly, or directed medially towards the back of the aorta.²⁸⁷

The anatomy of the LAA is highly variable in terms of its size, shape, and number of lobes. In approximately 54% of the population, the LAA is composed of two lobes, and in one-third of the population is composed of three lobes, with the lobes often lying in different planes. The shape of the LAA orifice can also vary and can be classified into five types, including oval (most common, 69%); foot-like (10%), triangular (8%); water drop-like (8%); and round (6%). The LAA ostium typically lies horizontal to the left superior PV but can also be superior or inferior to it.

Most often, the LAAs are classified into four morphological groups (Fig. 15.67): (1) chicken wing (most common, 48%): an LAA with an obvious bend in the proximal part of the dominant lobe or folding back of the LAA anatomy on itself at some distance from the perceived LAA ostium; (2) cactus (30%): an LAA with a dominant central lobe with secondary lobes extending from the central lobe in both superior and inferior directions; (3) windsock (19%): an LAA with a dominant lobe of sufficient length (greater than 4 cm) as the primary structure; and (4) cauliflower (3%): an LAA with limited overall length (less than the LAA ostium) and with more complex internal characteristics. These various LAA configurations can influence device/size selection and implantation success.

The LAA has long been recognized as the site of thrombus formation in most patients with nonvalvular AF. The LAA, with its trabeculations, provides the appropriate setting during fibrillation for blood stasis and thrombus formation. LAA morphology appears to be associated with different degrees of thromboembolic risk, with chicken wing morphology exhibiting the least stroke risk (4% vs. 10% to 18%). In addition, an increased number of lobes is associated with a higher risk of

LAA thrombus. Of note, the degree of pectinate trabeculations appears to be mild in LAAs with chicken wing morphology, moderate in cases with a cactus morphology, and extensive in LAAs with a cauliflower morphology.

The specific varying shapes of the LAA and its orifice have important implications for device closure of the appendage. All current closure devices of which all are circular in shape, and may not always conform to the LAA ostium. Furthermore, a horn-shaped configuration of the LAA (with a wide ostium and narrow “landing zone” [i.e., the area within the LAA where the device will be positioned]) can pose higher risk of device dislodgement. In these patients, choosing a device large enough to cover the ostium and yet maintain the optimal degree of oversizing in the landing zone (i.e., the area within the LAA where the device will be positioned) to secure anchorage can be a challenge. Also, LAA configuration can impact device design selection. Amplatzer devices are implanted in a relatively proximal position in the LAA (as compared to the Watchman device), which can be of advantage in relatively shallow LAAs and those with complex anatomy.

Left Atrial Appendage Imaging

Preprocedural imaging of the LAA is used to screen suitable candidates and to define LAA morphology and dimensions as well as exclude the presence of intracardiac clots.

TEE is the gold standard for thrombus detection within the LAA, and is also used to assess the shape and size of the LAA ostium, the width of the landing zone, the length of the LAA and—if possible—the number, shape, and location of the lobes.

Although TEE alone is commonly utilized for LAA morphology and measurements, it may not be sufficient for challenging LAA morphology. Cardiac CT angiography provides superior spatial resolution for assessment of LAA configuration, which has additional advantages for procedural preplanning (e.g., selecting device type, decision on device implant position and angles) aside from sizing measurements.²⁸⁸

Intraprocedurally, TEE and contrast angiography are commonly utilized to assess device sizing, guide device delivery and deployment, and assess adequacy of LAA closure. The utility of ICE has not been well established, but ICE is likely inferior to TEE for these purposes. Reliance on any particular imaging modality will depend on the expertise of the operator and institution. TEE images are recorded at set angles according to recommendations by the product manufacturers. For instance, for the Watchman device, diameters and depths were measured at 0 degree, 45 degrees, 90 degrees, and 135 degrees (Fig. 15.68). For Amplatzer devices, landing zones are measured at short-axis and long-axis views. Angiography of the LAA is performed in several views (RAO

Fig. 15.67 Morphological Types of the Left Atrial Appendage (LAA). Segmented computed tomographic images of the LAA in four different patients.

Fig. 15.68 Left Atrial Appendage (LAA) Closure With the Watchman Device. Transesophageal echocardiography (TEE, A and B) and fluoroscopic images (C–H, caudal right anterior oblique projections) during implantation of the Watchman device. (A) TEE measurements of the LAA diameter and depth at 45-degree angle. (B) TEE Doppler image at the same angle showing the Watchman device fully deployed in the LAA, with no flow jet in the LAA around the device. Flow can be seen in the left superior pulmonary vein (PV) adjacent to the LAA. (C) The access sheath and a pigtail catheter are positioned within the LAA. (D) Contrast angiography (via the pigtail catheter) is performed to delineate LAA anatomy. Note the three radiopaque marker bands (blue arrowheads) on the access sheath used for device sizing. (E) The Watchman device is positioned within the access sheath. The length of the device (blue arrow) corresponds to the marker band indicating the LAA ostium. (F) The Watchman device is partially unsheathed. (G) The Watchman device is fully deployed in the LAA, but still connected to the delivery catheter. Contrast angiography (via the access sheath) reveals no peri-device leak. (H) The Watchman device is released. LA, Left atrium; LCX, left circumflex coronary artery; LV, left ventricle.

caudal and cranial projections typically outline the LAA best), delineating shape and size (see Fig. 15.68).²⁸⁸

Importantly, the LAA size is dependent on the loading status as well as on the presence of sinus rhythm or AF. Therefore to avoid undersizing the LAA, it is recommended to assess LAA dimensions during the procedure after establishing a mean filling pressure in the LA in the high normal range (greater than 10 mm Hg). Infusion of normal saline can be required to optimize volume status.

Left Atrial Appendage Catheterization

Percutaneous LAA occlusion is usually performed under general anesthesia and with TEE and fluoroscopic guidance. LA access is achieved via a transseptal puncture. A puncture site at inferoposterior aspect of the septum is recommended to enhance access to the LAA. Anterior septal puncture (or through a patent foramen ovale) should be avoided due to difficulty to turn the guide catheter adequately to the anteriorly located axis of the LAA. TEE (or ICE) is used to guide atrial septal puncture. IV heparin is administered immediately after or, preferably, before LA access, and the ACT is maintained above 250 seconds.

After the transseptal puncture, an extra-stiff 0.035-inch guidewire is positioned into the left superior PV and the transseptal sheath is exchanged over the wire for the access catheter. To position the access catheter into the LAA, an angiographic catheter is advanced through the access sheath over a soft J-tipped 0.035-inch wire. The sheath and pigtail catheter are withdrawn slightly from the left superior PV and turned counterclockwise to fall into the ostium of the LAA. Then, the pigtail catheter is positioned into the distal portion of the LAA, and the access sheath is subsequently advanced over the pigtail catheter until the proximal marker band corresponding to the maximum device diameter is at or just distal to the LAA ostium. Great care needs to be taken to avoid damage to the fragile and thin-walled LAA during catheter placement; manipulating the access sheath in the LAA without an adjunctive device (pigtail catheter) and advancing past pigtail loop should be avoided. Once the access sheath is in proper position, pigtail catheter can be removed.

Watchman Device Device Specifications

The Watchman device is a self-expanding, nickel titanium (nitinol)-framed structure. The device has fixation barbs facing the circumference of the appendage (to minimize dislodgement and embolization) and a permeable polyethylene terephthalate membrane that covers the surface of the device facing the LA. Watchman devices come in 5 sizes (21, 24, 27, 30, and 33 mm) to accommodate varying LAA anatomy and size.

The Watchman device is attached to a delivery cable and is delivered through a dedicated 14 Fr sheath with 12 Fr inner diameter and 75-cm working length. The access sheaths come in a double- or single-curve configuration to accommodate varying appendage orientation. There are 3 radiopaque marker bands (33, 27, and 21 mm) on the distal sheath, which should be aligned to the LAA ostium according to the selected device size (see Fig. 15.68).

Device Sizing

The device size is typically chosen 10% to 20% larger than the diameter of the landing zone within the LAA body (measured on TEE from the area of the left circumflex coronary artery across the LAA to 1 cm inward from the tip of the ridge separating LAA and left superior PV). The oversizing allows for sufficient device compression and stable positioning. The device is not recommended for LAAs with diameters less than 17 mm or more than 30 mm, or when the LAA length is less than the diameter of the landing zone.

Device Deployment

The access sheath has three markers corresponding to device size and is advanced into the LAA until the marker aligns with the ostial plane of the appendage (see Fig. 15.68). After purging, the device is advanced via a delivery catheter in the access sheath until the marker of the device catheter matches the most distal marker on the access sheath. Then, the access sheath is pulled back over the device until the device catheter and access sheath are connected. At this point, no further advancement of the device is permitted (to avoid LAA injury). Once the proper position of the sheathed device within the LAA is confirmed by biplane fluoroscopy and TEE, the device is deployed (unsheathed) by retracting the access sheath and delivery catheter simultaneously while maintaining device position (see Fig. 15.68). Once deployed, angiography and TEE are used to verify proper positioning and stability.

To avoid device embolization, several criteria must be confirmed via fluoroscopy and TEE before device release, including: (1) Position: the plane of maximum diameter of the device should be at or just distal to the orifice of the LAA, and should not protrude greater than 4 to 7 mm beyond the LAA ostium (depending on device size outlined in the manufacturer's instructions for use manual); (2) Anchor: a tug test is performed under fluoroscopy or TEE monitoring to confirm proper anchoring; the access sheath is withdrawn 1 to 2 cm from the face of the device and the deployment knob is gently retracted and released, demonstrating simultaneous movement of the device and appendage; (3) Size: the plane of the maximum device diameter is measured using TEE in the 4 standard views: 0, 45, 90, and 135 and ensure the thread is visible. When properly sized, the maximum diameter of the device is 80% to 92% of its original size (i.e., device compression of 8% to 20%). Device compression ensures the device exerts enough radial force to keep it stable against opposing LAA walls; and (4) Seal: the device should cover the entire LAA ostium, with all LAA lobes being distal to the device, and with no or minimal (less than 5 mm by color Doppler) residual flow around the margins of the device. If the device release criteria are satisfactory, the device is released by counterclockwise rotation of the delivery catheter (see Fig. 15.68).²⁸⁹

If one or more of those criteria appears suboptimal, the device can be retrieved and exchanged or repositioned. The recaptured device can be withdrawn but cannot be advanced within the LAA. Therefore if the device is too deep in the LAA, it has to be recaptured and repositioned more proximally. If the device is too proximal, a complete recapture and exchange of the device are necessary.

Postoperative Management

All Watchman-implanted patients in the United States are required to take warfarin for at least 45 days postimplantation. TEE is performed at 45 days, 6 months, and 12 months to evaluate for residual peridevice flow. Warfarin is discontinued if the LAA closure is complete or the width of the flow jet is less than 5 mm on color Doppler. Once warfarin is stopped, dual antiplatelet therapy with aspirin and clopidogrel are prescribed until completion of 6-month follow-up. Following 6-month follow-up, aspirin alone is prescribed indefinitely. Long-term warfarin is continued in patients without adequate LAA closure.¹²² NOACs or dual-antiplatelet therapy instead of warfarin early after LAA closure with the Watchman device were found safe in recent reports, but these treatment strategies have not yet been confirmed in large studies.^{290,291}

If surveillance TEE at 45 days shows incomplete LAA seal, with a peridevice flow jet greater than 5-mm, warfarin must be continued, and follow-up TEE in another 3 months should be performed. If the leak remains greater than 5 mm, the implant is considered a failure and the patient needs to remain on oral anticoagulation.

Outcome

A recent meta-analysis of two randomized clinical trials and two non-randomized registries demonstrated high procedural success rates of LAA occlusion with the Watchman device; more than 93% of device patients discontinued warfarin by 1 year. LAA closure was noninferior to long-term warfarin therapy for the composite outcome of stroke, systemic embolism, and cardiovascular/unexplained death. All-cause stroke rates were similar between groups, but the pathophysiology of stroke was significantly different; more warfarin patients experiencing hemorrhagic strokes and more Watchman patients experiencing ischemic strokes. In addition, all-cause bleeding was similar between groups; however, when periprocedural bleeding was excluded, bleeding rates were significantly lower in the Watchman group (likely related to withdrawal of chronic anticoagulation therapy in device patients). However, this reduction in hemorrhagic stroke was balanced by a relative increase in ischemic stroke. In fact, ischemic strokes continue to occur after 1 year following LAA closure. Of particular concern, these late ischemic strokes may be related to late thrombus formation on the Watchman device in the absence of anticoagulation. The increased risk of ischemic stroke may relate to possible technical failures of the device: failure to completely obliterate LAA flow, anatomic remodeling of the LAA ostium over time resulting in more leaks, or the development of thrombus on the device.²⁹²

Device-related thrombosis remains a concern even after successful percutaneous endovascular Watchman device implantation. The risk is thought to be highest early after the implant, when endothelialization on the device is still incomplete. For this reason, the standard medical treatment after Watchman implantation, as studied in prospective trials, includes warfarin for 45 days. In the PROTECT-AF (Watchman Left Atrial Appendage System for Embolic Protection in Patients With Atrial Fibrillation) trial, device-related thrombosis was observed in 5.7% of patients, with thrombosis occurring less frequently at 45 days (with patients still taking warfarin) compared to 6 or 12 months (device-related thrombus rates 1.4%, 3.9%, and 2.5%, respectively), suggesting that anticoagulation therapy early after Watchman implant is protective. Interestingly, the rate of device-associated thrombosis was comparable in observational studies investigating a dual antiplatelet regimen after endocardial LAA closure device implantation (Watchman and Amplatzer Cardiac Plug).^{290,293}

Other procedural complications include device migration, device embolization, cardiac perforation with tamponade, as well as systemic air or thrombus embolism.

Amplatzer Cardiac Plug

Device Specifications

The Amplatzer Cardiac Plug is a self-expanding nitinol platform with a distal lobe (which secures the device within the LAA) and a proximal disc (which seals the LA side of the LAA ostium). The lobe and disc are connected by a short flexible central waist, with two polyester patches sewn onto the two components. The lobe of the device is designed to conform to the inner wall of the LAA with a depth of 10 mm or more and is surrounded by fixation barbs to secure device placement and minimize the risk of embolization (Fig. 15.69). The flexible waist allows the disc to self-orient to the cardiac wall and facilitates conformation to variable appendage shapes. Unlike the Watchman device, the length of the Amplatzer Cardiac Plug is shorter than its diameter and, thus, it can be implanted in appendages that are shorter than wide. The lobe size ranges between 16 and 30 mm (with a step size of 2 mm). The diameter of the disc is 4 or 6 mm larger than the lobe for the 16 to 22 mm or 24 to 30 mm devices, respectively.

The Amulet, a second-generation Amplatzer Cardiac Plug, has been designed with strategic modifications at improving device stability and

sealing performance as well as reducing thrombus formation on the atrial side of the device, without changing the main design of the original Amplatzer Cardiac Plug (see Fig. 15.69). These modifications include a longer distal lobe, larger diameter of the proximal disc, longer waist between the distal lobe and the proximal disc, recessed end-screw on the proximal disc, and more fixation barbs. The Amulet comes in eight sizes to seal LAAs with landing zones from 11 to 31 mm in diameter. Also, the more proximal device positioning within the LAA allows for placement regardless of distal anatomy or existence of multiple distal lobes. The longer waist allows for more flexible placement within the LAA and better conformation to angles between the LAA body and ostium.^{294,295}

Device Sizing

In general, the Amplatzer Cardiac Plug lobe size is typically chosen 1.5 to 3 mm larger than the widest diameter of the landing zone within the LAA body (measured in both short-axis and long-axis views on TEE at 10 mm within the LAA orifice perpendicular to the neck axis). With the new Amulet, a larger oversize is recommended: 3 to 5 mm for 16- to 22-mm devices and 3 to 6 mm for 25- to 34-mm devices. The oversizing improves stability of the device and proper anchoring of the lobe. The Amplatzer Cardiac Plug is not recommended for LAAs with diameters more than 29 mm (more than 31 mm for the Amulet) or with length less than 10 mm (less than 7.5 mm for the Amulet).²⁹⁴

Device Deployment

With the delivery sheath at least 15 mm inside the LAA, the first half of the device (lobe) is deployed by withdrawing the delivery sheath, and after confirming the optimal position by TEE and fluoroscopy, the remainder of the lobe is deployed by pushing it out. Once the optimal angle and position of the lobe at the landing zone are confirmed, the disc is deployed by further retracting the sheath while still gently pushing on the device (eFig. 15.29).²⁹⁴

Device release criteria include: (1) Position: the lobe should not protrude more than one-third beyond the left circumflex artery on TEE; (2) Anchor: a tug test is performed under fluoroscopy or TEE monitoring to confirm proper anchoring; (3) Size: the lobe should be visibly compressed (tire shape) with an appreciable separation of lobe and the disc; and (4) Seal: the disc should assume a slightly concave shape and cover the entire LAA orifice and provide apposition against the chamber wall under gentle tension, with no or minimal residual flow around the margins of the device. If the device release criteria are satisfactory, the device is released by counterclockwise rotation of the delivery cable. If one or more of those criteria appears suboptimal, the device can be retrieved and exchanged or repositioned.²⁸⁹

Postoperative Management

Currently, directions for use of the Amplatzer Cardiac Plug and the Amulet recommend dual antiplatelet therapy for 3 months followed by aspirin alone. In the absence of randomized trials and rigorous follow-up, the significance of device-related thrombosis is not entirely known, but this risk remains a concern. Some investigators have advocated more individualized anticoagulation regimens after LAA occlusion with the Amplatzer devices. A short course of anticoagulation therapy (similar to that used following Watchman) can potentially reduce the risk of early thrombus formation, especially in patients with markers of increased risk of thrombus formation.²⁹⁶

Outcome

The initial Amplatzer device used for LAA occlusion was the Amplatzer septal occluder. The Amplatzer Cardiac Plug is the first dedicated Amplatzer device specifically designed for LAA closure. The Amplatzer

Amulet device is a second-generation Amplatzer LAA closure device that is an evolution of the Amplatzer Cardiac Plug.

To date, the published reports of the Amplatzer Cardiac Plug and the Amulet are not as robust as those of the Watchman device. These devices are available outside of the United States, and they have been marketed for use with antiplatelet therapy only, albeit with little supportive evidence.

Several nonrandomized studies in AF patients with contraindications to systemic anticoagulation showed favorable efficacy and safety outcomes. The incidence of device-associated thrombosis has varied among different studies from 3% to 17%.¹²²

In the largest report of the Amplatzer Cardiac Plug data from 1047 consecutive patients treated in 22 centers, procedural success was 97%,

with a 5% rate of major adverse events. Follow-up TEE (performed in only 63% of patients) revealed device-related thrombosis in 4.4%. The annual rate of systemic thromboembolism was 2.3%, and that of major bleeding was 2.1%. However, in other reports, device-related thrombosis was observed on routine TEE follow-up in up to 17% of patients during treatment with dual antiplatelet therapy. The risk of thrombosis increases with incomplete LAA closure. Notably, thrombosis appeared to originate from the central end-screw of the device in a significant proportion of cases. In addition, placing the disc deeper within the LAA results in cul-de-sac formation that may exhibit low flow and the potential for thrombus formation.^{296,297}

Design modifications in the second-generation Amplatzer device (Amulet) were aimed to reduce thrombogenicity and improve LAA

seal. Nonetheless, a recent report found a high incidence of device-related thrombosis (17%) despite continued antiplatelet therapy.

PERCUTANEOUS LEFT ATRIAL APPENDAGE LIGATION

Currently the Lariat procedure is being performed in patients with AF who have a high risk of stroke and have relative or absolute contraindications to oral anticoagulation (e.g., such as recurrent bleeding, intracranial bleeding) and those in whom oral anticoagulation had been ineffective in preventing stroke.

Contraindications to the Lariat procedure include unamenable LAA size, morphology, or orientation (as evaluated on preprocedural cardiac CT angiography), intraatrial thrombi, and a history of conditions that would result in pericardial adhesions (e.g., pericarditis, open-heart surgery, thoracic radiation, and prior epicardial ablation).

A particular benefit of the Lariat device when compared with other endovascular devices, particularly the Watchman device, is that anticoagulation is not required preoperatively. Unlike other endocardial LAA occlusion devices, the Lariat leaves no foreign body in the endocardial surface of the LA. Hence, the Lariat procedure can be performed in patients with contraindications to anticoagulation. Nevertheless, early (1 month) and late (2 to 4 months) partial reopenings with bidirectional flow between the LAA and the LA have been reported following the Lariat procedure. Therefore some investigators have recommended short-term oral anticoagulation therapy (similar to the regimen used following the Watchman procedure) in patients with no absolute contraindications until complete LAA exclusion have been confirmed on follow-up TEE.²⁹⁸

A potential added benefit of the Lariat procedure, which is not shared by LAA plug devices, is that it results in electrical isolation of the LAA. Also, the Lariat procedure may be considered when the LAA is too large for either the Watchman or the Amplatzer Cardiac Plug devices, as long as the maximal ostial diameter is less than 40 mm.²⁹⁹

Left Atrial Appendage Imaging

Preprocedural imaging of the LAA with cardiac CT angiography and TEE is critical to assess the LAA anatomy, exclude LAA thrombus, and guide the placement of the endocardial and epicardial magnet-tipped guidewires.

Preprocedural CT angiography with 3-D reconstruction is important to identify LAA morphology and dimensions that are not compatible with the Lariat suture delivery device, including: (1) LAA diameter greater than 40 mm; (2) superiorly oriented LAA with the LAA apex directed behind the pulmonary artery; (3) multilobed LAA with different orientation in different planes exceeding 40 mm; and (4) a posteriorly rotated heart.^{299,300}

TEE can be used to confirm LAA morphology and rule out LAA thrombus, especially when there is incomplete filling of the LAA using CT angiography. Intraprocedurally, TEE and angiography are commonly used to guide delivery and deployment of the device, and assess adequacy of LAA closure.³⁰⁰

Device Specification

The Lariat system consists of the following components: (1) the Lariat suture delivery device; (2) two (0.025-inch endocardial and 0.035-inch epicardial) magnet-tipped guidewires (FindrWIRZ); (3) a large (15-mm) compliant occlusion balloon catheter; and (4) an epicardial sheath (13 Fr epicardial cannula) with compliant atraumatic tip.

The Lariat procedure is a percutaneous adaptation of the surgical exclusion of LAA with a suture. The suture material delivered by the Lariat snare is identical to the suture material used during open-heart

surgery to exclude LAA. The Lariat device is deployed by means of a trans-pericardial approach using an epicardial snare with a pretied suture to lasso and occlude the LAA.

To isolate the LAA, this system requires both endocardial and epicardial approaches. Initially, pericardial access is obtained (before administration of IV heparin) and an epicardial soft-tipped access cannula is inserted into the pericardial space. Then, transseptal puncture is performed and the endocardial magnet-tipped guidewire is advanced transseptally to the apex of the LAA. Via the percutaneous epicardial access sheath, the epicardial magnet-tipped guidewire is advanced towards the LAA to connect coaxially with the endocardially positioned magnet-tipped guidewire. The two guidewires form a rail at the LAA tip to facilitate advancing the Lariat device to snare and ligate the LAA. The lasso-like suture (snare) is advanced via the epicardial sheath over the epicardial magnet-tipped guidewire to the base of the LAA. The suture is then deployed to strangulate the LAA.²⁸⁹

Epicardial Access

The pericardial access is achieved via the subxiphoid approach, as described in **Chapter 4**. Preprocedural CT angiogram is used to identify anatomic landmarks and guide the trajectory of the pericardial needle that would provide the most direct access to the LAA. The needle-in-needle technique is preferred to minimize the risk of RV injury. An anterior pericardial approach is required to facilitate maneuvering the Lariat suture delivery device over the anterior surface of the RV and posteriorly toward the tip of the LAA in its most anterior aspect. A posterior pericardial access results in the Lariat device approaching the LAA toward its lateral aspect, thus precluding the snare from going over the anteriorly directed apex of the LAA. Also, a pericardial access that is too medial makes it difficult to direct the Lariat suture delivery device posteriorly toward the apex of the LAA.

The combined use of the anteroposterior and left-lateral fluoroscopic views is recommended to assure anterolateral pericardial access. In the anteroposterior fluoroscopic view, the needle is directed toward the left shoulder, just lateral to the pulmonary artery and the hilum of the pulmonary vasculature. In the left lateral fluoroscopic view, the needle is directed to the anterior surface of the RV, 1 to 2 cm above the apex of the heart.³⁰⁰

Once pericardial access is obtained, serial dilators are used to dilate the epicardial access route and a 13 Fr soft-tipped guide cannula and its dilator are advanced over the guidewire into the pericardial space. There is a curve at the end of the epicardial sheath (marked by the black colored flat surface of the proximal end of the sheath) that should be directed away from the surface of the heart (i.e., the black-colored flat surface is oriented at 12 o'clock) when advancing the sheath. The dilator and the sheath are advanced over the superior aspect of the RV until the tip of the dilator approaches the edge of the cardiac silhouette in the anteroposterior view. The black flat surface of the sheath is then slowly rotated to 9 o'clock and the sheath is then advanced over the dilator until it nears the tip of the dilator, and the dilator is then removed. The dilator and the sheath should never be advanced into the pericardial space without the guidewire. Similarly, the sheath should never be advanced without the dilator or the Lariat device.

Endocardial Access

An inferoposterior septal puncture site is recommended to facilitate access to the LAA. A higher transseptal puncture or transseptal access through a patent foramen ovale tends to direct the transseptal sheath toward the left PVs and make it difficult to engage the anterior part of the LAA with the endocardial magnet wire.³⁰⁰

A pigtail catheter is advanced over the guidewire into the LAA and contrast angiography is performed to assess the LAA size and

orientation. Then, the pigtail catheter is removed and the occlusion balloon catheter and the endovascular magnet-tipped guidewire are advanced (as a unit) into the LAA. The endovascular magnet-tipped guidewire is then carefully navigated to the distal end of the LAA and is stabilized (Fig. 15.70). The endocardial magnet-tipped guidewire should be placed in the most anterosuperior aspect of the LAA (in the 30-degree LAO or 90-degree left-lateral fluoroscopic views). An angiogram (through the occlusion balloon catheter) is performed to confirm guidewire placement. Subsequently, the balloon is inflated and positioned just distal to the ostium of the LAA. Once proper position is confirmed on TEE and angiography, the balloon is deflated.

Connecting the Epicardial and Endocardial Magnet-Tipped Guidewires

The epicardial magnet-tipped guidewire is then introduced into the pericardial space through the epicardial sheath and carefully navigated toward the endocardial magnet-tipped guidewire until both magnets connect end to end (see Fig. 15.70). Coaxial alignment of the two guidewires (as confirmed on RAO and LAO fluoroscopic views) is necessary to provide a monorail for the Lariat device, and is facilitated by proper positioning of the endocardial magnet in the anterior aspect of the LAA and correct orientation of the epicardial sheath.

Snaring the Left Atrial Appendage

The Lariat is back-loaded over the epicardial magnet-tipped guidewire and, with the snare closed, advanced over the guidewire into the pericardial sheath. The curve at the end of the Lariat device should be aligned to that of the epicardial sheath to facilitate the anterior-to-posterior direction the snare must travel within the pericardial space to advance over the apex of the LAA. The correct orientation of the snare within the pericardial space is confirmed when the radio-opaque marker on the distal end of the Lariat device is on the left side in the 30-degree LAO fluoroscopic view and the legs of the snare are parallel.³⁰⁰

While maintaining the orientation of the flat surface of the Lariat handle and the flat/black end of the pericardial sheath together, the Lariat device is carefully advanced over the epicardial magnet-tipped guidewire. Once past the pericardial sheath, the snare is opened fully in the pericardial space.

The Lariat suture system is guided along the epicardial guidewire (under fluoroscopic monitoring) and looped over the LAA, while maintaining the magnets in the same position and avoiding excessive slack or tension on the epicardial guidewire. Occasionally, gentle rocking of the device and manipulation (rotating as well as advancement or retraction) of the sheath can help facilitate the advancement of the snare over the LAA. If the magnets detach anytime during this process, then the Lariat suture system is retracted and the magnets are reengaged.

Subsequently, the occlusion balloon is inflated at the LAA ostium. The fluoroscopic markers on the balloon can be used to ensure that the Lariat has been fully advanced over the LAA ostium. Multiple fluoroscopic views and TEE are used to confirm the position of the Lariat snare and verify that all the lobes of the LAA are beyond the Lariat suture. At that point, the snare is tightened to approximate the tissue (see Fig. 15.70). LA angiography and Doppler TEE are used to ensure complete closure of the LAA (less than 1 mm flow on cross-section). If the position of the snare is not satisfactory, the snare can be released and repositioned to capture the intended closure site.

Once satisfactory exclusion of the LAA by the closed snare is confirmed, the occlusion balloon is deflated and the magnet-tipped guidewires are disconnected by pulling the endocardial guidewire while holding the epicardial guidewire. The deflated balloon and endocardial guidewire are then removed from the LAA. The preloaded, pretied suture is then released from the snare and tightened. LAA closure is verified again

with angiography and TEE (see Fig. 15.70). The Lariat device is then pulled back off the LAA and, after a few minutes, complete LAA closure is confirmed one more time with angiography and TEE. If closure is incomplete, the Lariat can be readvanced over the LAA and tightened again. Once complete LAA closure is verified, the suture is cut. All the wires and sheaths are then retracted and a pericardial drain is placed and will be left in place.³⁰⁰

Postoperative Management

A pericardial drain is left in place for the next 24 to 48 hours to allow for prompt management of potential pericardial effusion. The drain may be removed once the absence of reaccumulating effusion is verified on echocardiographic examinations over a 24-hour period. Antibiotic therapy is administered as long as the pericardial drain is in place.

Colchicine is frequently used to reduce pain associated with pericarditis and the prevention of Dressler syndrome. Colchicine is usually initiated on the day of the procedure and maintained for 3 to 4 weeks. Nonsteroidal antiinflammatory drugs can be added to colchicine. Oral corticosteroids can be considered for severe or persistent pericarditis.³⁰⁰

Surveillance TEE is recommended at 4 to 6 weeks after the procedure to assess thrombus and leaks. If there is a leak, a repeat TEE at 3 to 6 months is recommended. In patients with no absolute contraindications, it may be prudent to continue oral anticoagulation postoperatively until surveillance TEE excludes the presence of persistent LAA leak and thrombus formation. Dual antiplatelet therapy (aspirin and clopidogrel) or aspirin alone can be considered in patients who cannot tolerate short-term oral anticoagulation.³⁰⁰

Outcome

The Lariat suture delivery device is a suture snare catheter that is FDA approved for tissue approximation. Although the FDA approval does not specify the use of the device as a tool to ligate the LAA to decrease the risk of stroke, and despite the lack of evidence for device effectiveness and safety for that purpose, the Lariat procedure has been performed in a substantial number of patients in the United States as well as internationally, primarily to reduce the risk of stroke in AF patients with contraindications to oral anticoagulation therapy.¹²²

There have been no randomized controlled trials investigating the Lariat device to date. Recent studies evaluating the safety and efficacy of the Lariat device have reported acute procedural success rates exceeding 90%. Although several thousand Lariat procedures have been performed so far in the United States, the true safety profile of the Lariat device is yet to be fully characterized.

In a retrospective, multicenter study of 154 consecutive patients, device success (defined as Lariat suture deployment with less than 5 mm leak) was 94%, and major complications occurred in 10%, including 1 death due to respiratory failure and 14 major bleeds, 3 of which required emergent surgery. Complete LAA closure on follow-up TEE was maintained in 79% of patients, while leaks of less than 5 mm were observed in 14%, and leaks of greater than or equal to 5 mm in 6%. The true incidence and clinical significance of post-Lariat leaks have not been well defined and will require further investigation.¹²²

A recent review of the FDA MAUDE (Manufacturer and User Facility Device Experience) database revealed high rates of procedure-related mortality and morbidity, prompting the FDA to issue a safety alert to health care providers and patients about these issues. More recently, in a large study of 712 patients undergoing the Lariat procedure, the overall acute success rate with Lariat deployment is 95.5%. Follow-up TEE showed a leak of 2 to 5 mm in 6.5% and a thrombus in 2.5%. One patient had a leak of greater than 5 mm. Cardiac perforation occurred in 3.5%, with less than half of cases requiring surgical repair. Delayed complications (pericarditis requiring protracted treatment, and pericardial

Fig. 15.70 Percutaneous Left Atrial Appendage (LAA) Ligation Using the Lariat Device. Transesophageal echocardiography (TEE, A and B) and fluoroscopic images (C–H, caudal right anterior oblique projections) during Lariat ligation of the LAA. (A) TEE at baseline showing the LAA. (B) TEE Doppler image after LAA ligation showing obliteration of the LAA, with no flow jet in the LAA. Flow can be seen in the left superior pulmonary vein (PV) adjacent to the LAA. (C) After obtaining pericardial access (pericardial guidewire is visualized), left atrial (LA) access is obtained via a transseptal atrial puncture. The transseptal sheath and a pigtail catheter are positioned within the LAA. Contrast angiography of the LAA is performed to delineate LAA anatomy. (D) The endocardial magnet-tipped guidewire is placed in the most anterosuperior aspect of the LAA. The balloon is inflated and positioned just distal to the ostium of the LAA. (E) The epicardial magnet-tipped guide wire is advanced via the pericardial sheath and navigated toward the endocardial magnet-tipped guidewire until both magnets connect end to end. Then, the Lariat is guided along the epicardial guidewire, and the snare is tightened around the base of LAA. Exclusion of the LAA by the closed snare is confirmed by angiography (via the transseptal sheath). (F) The occlusion balloon is deflated and the magnet-tipped guidewires are disconnected. The preloaded, pretied suture is then released from the snare and tightened. (G) LAA closure is verified again with angiography. (H) The Lariat device is then pulled back off the LAA. Contrast angiography (via the transseptal sheath) of the LA (arrowhead delineate the LA border outlined by the contrast dye) confirms complete exclusion of the LAA. LV, Left ventricle.

and pleural effusion after discharge) occurred in 4.8%. Some technical modifications appear to have improved procedure safety in this study as compared to previous studies, including the use of micropuncture needle to access the pericardial space (which reduced the incidence of pericardial perforation), and the periprocedural use of colchicine (which reduced the incidence and severity of pericarditis).³⁰¹

It is important to note the Lariat procedure can potentially fill a void of therapeutic options for patients who cannot take oral anticoagulation. However, appropriate patient selection is critical for procedure success and safety. LAA size and anatomy should be carefully evaluated prior to the procedure. In a recent large study, almost 25% of patients who were initially thought to be Lariat eligible were excluded because of anatomic issues.³⁰¹

The role of LAA ligation seems to extend to arrhythmia reduction as well. The LAA can potentially play an important role in initiation and perpetuation of AF, which can be responsible for arrhythmia recurrence following PV isolation procedures. Hence, electrical isolation of the LAA is being increasingly considered in selected patients. Endocardial RF ablation has been traditionally used to achieve electrical isolation of the LAA. In patients undergoing cardiac surgery and epicardial ablation for AF, LAA ligation or excision has been shown in some (but not all) studies to enhance arrhythmia-free survival. Recently, percutaneous ligation of the LAA using the Lariat procedure was found to result in both mechanical and electrical exclusion of LAA, likely secondary to ischemic necrosis of the LAA distal to the ligation site. Initial reports have demonstrated a potential value this procedure as adjunct to catheter ablation of nonparoxysmal AF. The value of sequential Lariat ligation of the LAA with AF ablation is being evaluated in patients with persistent AF is currently being investigated.^{301–304}

Pericardial Bleeding

Intrapericardial bleeding can complicate the pericardial access as well as the atrial septal puncture (see Chapter 4). Further, bleeding can result from perforation of the LAA during placement of the magnet-tipped guidewire or snaring the LAA, and LAA laceration or avulsion during tightening of the suture.³⁰⁰

Pericardial bleeding related to the epicardial access procedure is most commonly a result of RV puncture. Laceration of the myocardium or epicardial vessels can occur during manipulation of the pericardial sheath. The use of the “needle-in-needle” technique can help reduce the risk of significant bleeding in the setting of inadvertent RV puncture. Also, careful sheath manipulation and leading with a guidewire before advancing or moving the curl of the pericardial sheath are imperative to reduce the risk of abrasion or laceration of pericardial structures.

RV puncture is usually benign if only the needle or guidewire has entered the chamber in a patient who is not anticoagulated. It is not uncommon to aspirate 10 to 30 mL of bloody drainage from the pericardial sheath early in the procedure. At this point, anticoagulation should not have been administered; therefore any bleeding should be self-limited and is generally considered a minor complication because it is not necessary to interrupt the procedure. Systemic anticoagulation with IV heparin is started when subsequent atrial transseptal puncture is performed, but only after verifying the absence of continued pericardial bleeding. However, persistent or severe pericardial bleeding can occur, occasionally requiring surgical intervention. Therefore precautions must be in place for managing severe bleeding, including availability of appropriate surgical expertise.³⁰⁰

The risk of LAA laceration or avulsion can be increased by overprolapsing or twisting the Lariat device during tightening of the suture. In addition, ligating the LAA distal to its ostium or releasing the suture on only one lobe of a multilobed LAA can increase the likelihood of tearing the LAA due to the friability and thinness of the LAA tissue.³⁰⁰

Pericarditis

Pericarditis is a common complication of the Lariat procedure, and likely the result of the profound inflammatory response to LAA ligation. Postprocedural pericarditis typically manifests as precordial discomfort and friction rub, and often is mild and self-limiting, resolving within a few days with oral nonsteroidal antiinflammatory agents. It is important to note that inflammatory pericarditis can render the epicardial space percutaneously inaccessible for repeat procedures.²⁹⁸

Prophylaxis with colchicine or nonsteroidal antiinflammatory drugs is often used to prevent Dressler syndrome. Oral steroids may be considered for the treatment of refractory cases. Although injection of steroids into the pericardial space has been used following epicardial ablation procedures to help reduce postprocedural pericarditis, this approach has not been recommended following LAA ligation due to the concern of potential interference with the healing process necessary for the complete chronic closure of the LAA. A transthoracic echocardiogram is recommended 7 days after the procedure if the patient has persistent pericarditis to assess for a pericardial effusion (Dressler syndrome). Late pericardial effusion can be transudative or exudative and may represent volume retention from reduced ANP release after LAA ligation.²⁹⁸

Incomplete Appendage Closure and Thrombus Formation

Percutaneous suture ligation of LAA results in extensive inflammation of LAA leading to fibrosis, scarring, and permanent closure of LAA, with complete endothelialization of the endocardial surface at suture site. The inflammatory reaction can also involve the LA, which can potentially promote thrombus formation.

A 2.2% incidence of LAA orifice thrombus has been reported during follow-up surveillance. Thrombus formation can result from an inflammatory reaction at the ligation site, epithelial denuding at the LAA orifice during balloon catheter retrieval, and suboptimal suture deployment. Loosening of the knot and tissue necrosis at the suture site are potential mechanisms of thromboembolic complications.

Incomplete LAA ligation after Lariat is not uncommon. In a significant proportion of patients undergoing the Lariat procedure, a partial LAA opening with a residual LAA cavity develops. In one report, intraprocedural residual flow into the LAA (leak) were observed in 10% of patients, while 32% had recanalized residual LAA cavities, which were morphologically similar to the original LAA, albeit significantly smaller in volume. Nonetheless, the Lariat device appears to be associated with a lower rate of leaks at 1 year as compared with the Watchman device. Further, the leaks following the Lariat procedure tend to be smaller and concentric (gunny sack effect), as compared to the eccentric leak (edge effect) following the Watchman procedure. The implications of a small leak (less than 5 mm) are unknown. If the leak is greater than 5 mm, alternate stroke prevention measures should be considered.^{305,306}

SURGICAL LEFT ATRIAL APPENDAGE EXCLUSION

Open surgical LAA amputation, suture ligation, or stapling is commonly performed in patients with AF who are undergoing valvular or coronary artery bypass surgery or as an adjunct to the maze procedure. In addition, various minimally invasive thorascopic LAA exclusion techniques (LAA excision, stapling, and clipping) have emerged as isolated surgical procedures or in conjunction with minimally invasive maze procedures for ablation of AF. Recently, thorascopic stand-alone LAA exclusion has been reported in a small group of patients with contraindications to anticoagulation. However, data are still limited regarding its efficacy and safety of these approaches. Also, dedicated LAA exclusion devices have been developed, including the AtriClip Device System (AtriCure, West Chester, OH, United States) and the Tiger Paw System (Maquet

Cardiovascular, Wayne, NJ, United States). Initial studies using the AtriClip demonstrated significant improvement in procedure success and safety.¹²²

An important limitation to surgical exclusion of the LAA is the high rate of incomplete exclusion of the LAA, which is said to range from 10% to 80%, depending on the surgical technique. Most clinical trials reported rates of successful LAA occlusion of only 55% to 66%. The highest success of complete LAA occlusion was with surgical excision and the lowest with LAA suture ligation or stapling. Dehiscence of the sutures can result in reopening of the LAA orifice or persistent flow between the appendage and the LA (eFig. 15.30).

The presence of incomplete LAA occlusion can promote thrombus formation secondary to blood stagnation, and is associated with a significantly higher risk of ischemic stroke/systemic embolization than complete LAA closure or LAA stump. In one report, 41% of patients with unsuccessful exclusion had LAA thrombus whereas there was none with excision. Furthermore, the rate of systemic thromboembolism in patients with incomplete LAA closure and not receiving oral anticoagulation therapy is three to five times greater than that predicted by CHADS₂ CHA₂DS₂-VASc score risk-stratification schemes. As such, routine postoperative screening for incomplete appendage ligation (by TEE or CT angiography) is recommended before discontinuation of anticoagulation therapy.³⁰⁷

Currently, no strong evidence exists to support the benefit of surgical LAA exclusion during routine cardiac surgery as a potential strategy to decrease the incidence of stroke in AF patients. In a meta-analysis of five clinical trials involving 1400 patients undergoing LAA exclusion or excision there appeared to be no clear benefit for LAA surgical exclusion, primarily due to the high rates of incomplete occlusion of the LAA as demonstrated by TEE. On the other hand, findings of a more recent meta-analysis suggested a potential benefit of surgical LAA resection in reducing the incidence of stroke in short- and long-term follow-up, although the statistical power was limited. Future prospective, randomized trials are necessary to definitively assess the long-term benefits and risks of LAA exclusion during cardiac surgery.³⁰⁸

Dotted (behind left superior pulmonary vein [LSPV])/dashed white lines indicate the actual orifice of the LAA, where ligation should have occurred. LIPV, Left inferior PV; RSPV, right superior PV; RIPV, right inferior PV.

Video 15.1 Left Atrial Appendage Imaging: Intracardiac Echocardiography (ICE). ICE imaging of the LAA showing a thrombus in the LAA. Images are obtained with the ICE transducer positioned in the PA and then at the tricuspid annulus. LA, Left atrium; LAA, left atrial appendage; LV, left ventricle; PA, pulmonary artery.

Video 15.2 Circumferential Antral Pulmonary Vein Isolation: CARTO Merge. The CARTO-Merge Module allows for images from a preacquired computed tomography angiogram of the left atrium (LA) and pulmonary veins (PVs) to be integrated on the electroanatomic image of the cardiac chamber created with the CARTO system. Shown are posteroanterior (PA) view of the LA and a cardioscopic view of the antrum of the left inferior PV (LIPV). CARTO-3 allows visualization of both the ablation and ring catheters. A surface electrocardiogram lead and ablation catheter recording are continuously monitored. Real-time intracardiac echocardiography (ICE) of the LA, LIPV, and left ventricle (LV) is also obtained to monitor catheter positioning as well as to monitor for the potential development of pericardial effusion. The ring catheter is positioned at the ostium of the LIPV. Ablation is commenced at the posterior aspect of the LIPV antrum. Radiofrequency (RF) energy is delivered in short applications (for 2 to 5 seconds) at a higher power (50 W, irrigation rate 30 mL/min, maximum temperature 43°C). The ablation catheter is dragged continuously in small increments every 2 to 5 seconds during continuous RF delivery, and ablation is repeated at each site, if required, for many times throughout the procedure until the local atrial electrogram is completely eliminated.

Video 15.3 Mapping Gaps in Circumferential Pulmonary Vein Ablation Lines: Rhythmia Activation and Propagation Maps. Electroanatomic (Rhythmia) activation and propagation maps of the left atrium (LA) acquired during atrial pacing in a patient with prior history of catheter ablation of atrial fibrillation (circumferential pulmonary vein [PV] isolation and LA roof linear ablation). Propagation and activation maps demonstrate two conduction gaps in the previous circumferential ablation lines around the left-sided PVs. After radiofrequency (RF) ablation targeting the gaps, repeat activation map demonstrated complete PV isolation. LAA, Left atrial appendage; LIPV, left inferior PV; LSPV, left superior PV; MA, mitral annulus.

Video 15.4 Phrenic Nerve Function Monitoring Using Intracardiac Echocardiography (ICE). For monitoring right phrenic nerve function (during laser or cryoballoon isolation of the right superior pulmonary vein), a diagnostic catheter is positioned at the anterolateral aspect of the superior vena cava at a site above the level of ablation where the phrenic nerve can be consistently captured. ICE (with the transducer positioned in the inferior vena cava [IVC] at the level of the diaphragm and pointed at the liver) is used to continuously visualize hepatic movement from the diaphragmatic excursion, indicative of successful phrenic nerve capture during continuous pacing. Initially, hepatic movement is observed at the pacing rate. Later, hepatic movement decreases, indicating reduction of the strength of the diaphragmatic contraction and phrenic nerve injury.

Video 15.5 Right Superior Pulmonary Vein Occlusion: Transesophageal Echocardiography (TEE) Before and After Stenting. TEE in a patient with total occlusion of the right superior pulmonary vein (RSPV) postablation of atrial fibrillation. At baseline, the RSPV is completely occluded with no flow on color Doppler. After intervention, the stent is visualized at the ostium of the RSPV, and blood flow is now restored.

Video 15.6 Right Superior Pulmonary Vein Occlusion: Computed Tomography (CT) Before and After Stenting. Cardiac CT in a patient with total occlusion of the right superior pulmonary vein (RSPV) postablation of atrial fibrillation. Horizontal sections of the CT scan are arranged serially from cephalic to caudal direction demonstrating complete absence of the RSPV. Parasagittal sections of the CT scan are arranged serially from anterior to posterior direction demonstrating complete absence of the RSPV. Parasagittal sections of the CT scan are arranged serially from anterior to posterior direction following stenting of the RSPV demonstrate patent stent. A, Anterior; Ao, aorta; F, foot; H, head; L, left; LA, left atrium; LIPV, left inferior pulmonary vein; LV, left ventricle; LSPV, left superior pulmonary vein; P, posterior; PA, pulmonary artery; R, right; RA, right atrium; RIPV, right inferior pulmonary vein; RV, right ventricle.

Video 15.7 Pulmonary Vein Stenting. A series of angiograms in a patient with total occlusion of the right superior pulmonary vein (RSPV) postablation of atrial fibrillation. Angiography of the right pulmonary artery is performed. The levophase of the angiogram reveals filling of the left atrium mainly via the right inferior pulmonary vein (RIPV, which has mild ostial stenosis). However, the RSPV is absent due to complete occlusion. Note the severely reduced perfusion of the upper and middle lobes of the right lung compared to the lower lobe. Contrast injection in the antrum of the RSPV confirms complete occlusion of the vein. An angioplasty wire is advanced through the occluded vein. An angioplasty balloon is inflated in the RSPV. After stenting, venous flow is restored, and contrast injection at the antrum of the RIPV reveals patent RIPV and RIPV. Severe ostial stenosis of the right middle pulmonary vein (RMPV) is also observed.

Video 15.8 Atrioesophageal Fistula: Computed Tomography (CT). Cardiac CT in a patient with an atrioesophageal fistula postablation of atrial fibrillation (AF). Horizontal sections of the CT scan are arranged serially from cephalic to caudal direction demonstrating normal cardiac anatomy. Shown are CT scan prior to ablation and repeat CT scan performed 6 days postablation. Horizontal sections of the CT scan demonstrating air embolus into the left atrium (LA) and at the level of the MV. LV, Left ventricle; MV, mitral valve; NGT, nasogastric tube positioned in the esophagus.

Video 15.9 Pneumopericardium: Computed Tomography Scan of the Chest. Computed tomography scan of the chest was obtained in a patient presenting with chest pain 2 weeks after undergoing catheter ablation of atrial fibrillation. Air accumulation within the pericardial space is observed. No intracardiac air is observed.

Video 15.10 Left Atrial Appendage (LAA) Device Closure (Watchman Device). Fluoroscopic images are shown in the right anterior oblique (RAO) and left anterior oblique (LAO) views during LAA closure with the Watchman device. After transseptal atrial puncture, a pigtail catheter is advanced through the access sheath and used to facilitate catheterization of the LAA. Then, contrast angiography of the LAA is performed to assess LAA anatomy. Subsequently, the Watchman device is advanced via a delivery catheter in the access sheath until the marker of the device catheter matches the most distal marker on the access sheath. Contrast angiography is repeated to assess device sizing and guide device delivery and deployment. Once the proper position of the sheathed device within the LAA is confirmed by biplane fluoroscopy and TEE, the device is deployed (unsheathed) by retracting the access sheath and delivery catheter simultaneously while maintaining device position. Left atrium (LA) angiography is used to verify proper positioning and stability. A tug test is performed to confirm proper anchoring of the device; the access sheath is withdrawn 1 to 2 cm from the face of the device and the deployment knob is gently retracted and released. Then, the device is released by counterclockwise rotation of the delivery catheter.

Video 15.11 Transesophageal Echocardiography (TEE) Imaging of the Left Atrial Appendage During Watchman Device Placement. TEE imaging is performed at baseline to evaluate the size of the left atrial appendage (LAA) and exclude the presence of LAA thrombus. The dimensions of the LAA are measured in multiple angles. After deployment of the Watchman device, TEE is used to assess appropriate landing zone of the device, adequate device compression, and adequate seal of the LAA.

Video 15.12 Left Atrial Appendage (LAA) Device Closure: Watchman Device Partial Retrieval. Fluoroscopic images are shown in the right anterior oblique (RAO) and left anterior oblique (LAO) views during LAA closure with the Watchman device. After transseptal atrial puncture, a pigtail catheter is advanced through the access sheath and used to facilitate catheterization of the LAA. Then, contrast angiography of the LAA is performed to assess LAA anatomy. Subsequently, the Watchman device is advanced via a delivery catheter in the access sheath. Note proximal marker is more distal to the plane of the LAA ostium. The device is deployed (unsheathed) by retracting the access sheath and delivery catheter simultaneously while maintaining device position. Left atrium (LA) angiography and transesophageal echocardiography (TEE) images showed an inappropriately distal position of the Watchman device within the LAA, failing to seal the entire LAA ostium. Partial retrieval of the device was performed and the device was redeployed more proximally, with LA angiography and TEE images confirming appropriate device position.

Video 15.13 Watchman Device Implantation: Complete Device Retrieval. Fluoroscopic images are shown in the right anterior oblique (RAO) and left anterior oblique (LAO) views during left atrial appendage (LAA) closure with the Watchman device. After transseptal atrial puncture, a pigtail catheter is advanced through the access sheath and used to facilitate catheterization of the LAA. Then, contrast angiography of the LAA is performed to assess LAA anatomy. Note the noncoaxial engagement of the access sheath to the LAA. Subsequently, the Watchman device is advanced via a delivery catheter in the access sheath. The device is deployed (unsheathed) by retracting the access sheath and delivery catheter simultaneously while maintaining device position. LAA angiography and transesophageal echocardiography (TEE) reveals proximal and noncoaxial position of the Watchman device. Complete retrieval of the device was performed.

Video 15.14 Watchman Device Embolization. Fluoroscopic images are shown in the right anterior oblique (RAO) projection during left atrial appendage (LAA) closure with the Watchman device. After transseptal atrial puncture, a pigtail catheter is advanced through the access sheath and used to facilitate catheterization of the LAA. Then, contrast angiography of the LAA is performed to assess LAA anatomy. Note the shallow depth of the LAA compared to the width of the ostium. Subsequently, the Watchman device is advanced via a delivery catheter in the access sheath. The device is deployed (unsheathed) by retracting the access sheath and delivery catheter simultaneously while maintaining device position. LAA angiography and TEE reveals a proximal position of the Watchman device. The Watchman device could not be visualized on the chest x-ray performed on the day following the procedure. Therefore a CT scan of the chest was performed to look for the Watchman device. The device was found to have embolized into the abdominal aorta. The device could be retrieved via a trans-femoral arterial approach.

Video 15.15 Percutaneous Left Atrial Appendage (LAA) Ligation (Lariat): Transesophageal Echocardiography (TEE) Imaging. TEE imaging is performed at baseline to evaluate the size of the LAA and exclude the presence of LAA thrombus. After LAA ligation, TEE is used to assess adequate seal of the LAA. LA, Left atrium; LV, left ventricle; PV, pulmonary vein.

Video 15.16 Percutaneous Left Atrial Appendage (LAA) Ligation (Lariat). Fluoroscopic images are shown in the right anterior oblique (RAO) and left anterior oblique (LAO) views during percutaneous LAA ligation (the Lariat procedure). After transseptal atrial puncture, a pigtail catheter is advanced through the access sheath and used to facilitate catheterization of the LAA. Then, contrast angiography of the LAA is performed to assess A pigtail catheter is advanced over the guidewire into the LAA and contrast angiography is performed to assess the LAA size and orientation. Then, the pigtail catheter is removed and the endovascular magnet-tipped guidewire is advanced and carefully navigated to in the most anterosuperior aspect of the LAA. The epicardial magnet-tipped guide wire is then introduced into the pericardial space through the epicardial sheath and carefully navigated towards the endocardial magnet-tipped guidewire until both magnets connect end to end. The Lariat is back-loaded over the epicardial magnet-tipped guidewire and advanced to snare and ligate the LAA. Left atrium (LA) angiography is performed to confirm complete closure of the LAA.

ANATOMY AND PHYSIOLOGY OF THE SINUS NODE

The sinus node is a subepicardial, “crescent-” or “tadpole”-shaped structure located laterally within the epicardial groove of the sulcus terminalis of the right atrium (RA) at the junction of the anterior trabeculated appendage with the posterior smooth-walled venous component. The endocardial aspect of the sulcus terminalis is marked by the crista terminalis. Starting epicardially at the junction of the superior vena cava (SVC) and the right atrial appendage, the sinus node courses downward and to the left along the sulcus terminalis, to end subendocardially almost to the inferior vena cava (IVC). In adults, the sinus node measures 8 to 22 mm long and 2 to 3 mm wide and thick. The right phrenic nerve often runs in close proximity to the sinus node, where it lies on the fibrous pericardium immediately overlying the lateral and anterolateral quadrants of the SVC–right atrial junction (see Fig. 8.1).^{1–4}

The sinus node normally is the dominant pacemaker of the heart. Its pacemaker function is determined by its low maximum diastolic membrane potential and steep phase 4 spontaneous depolarization. Importantly, the pacemaker activity is not confined to a single cell in the sinus node; rather, sinus node cells function as electrically coupled oscillators that discharge synchronously because of mutual entrainment. Current evidence suggests a “pacemaker hierarchy” within the sinus node. At faster rates, the sinus impulse originates in the superior portion (head) of the sinus node, whereas at slower rates, the impulse arises from a more inferior part (toward the tail). The hierarchy mediates heart rate changes (in response to physiological stimuli) via a dynamic craniocaudal shift in the “leading pacemaker” site.

Notably, the sinus node is functionally insulated from the surrounding atrial myocytes, except at a limited number of different conduction pathways (exit sites) that allow transmission of sinus impulses to atrial myocardium, likely responsible for the variations in P wave morphology and polarity commonly observed at different sinus rates.^{3,5–7} Neural and hormonal factors influence both the site of pacemaker activation,

likely via shifting points of initial activity, and the point of exit from the sinus node complex.^{2,8–10}

PATHOPHYSIOLOGY

Sinus tachycardia is a physiological response to sympathetic activation and/or parasympathetic withdrawal. Inappropriate sinus tachycardia (IST) is a nonparoxysmal tachyarrhythmia characterized by a persistent increase in resting sinus rate unrelated to, or out of proportion of, the level of physical, emotional, pathological, or pharmacological stress, or an exaggerated heart rate response to minimal exertion or a change in body posture. IST is neither a response to a pathological process (e.g., heart failure, hyperthyroidism, or drug effects) nor a result of physical deconditioning. Crucial to this definition is the presence of associated symptoms.^{10–13}

The underlying mechanism(s) of IST is poorly understood and remains controversial. Potential mechanisms include enhanced automaticity, disorder of autonomic responsiveness of the sinus node, altered sinus nodal intrinsic regulation, and sympathovagal imbalance, with excessive sympathetic drive and/or reduced vagal influence on the sinus node. A primary abnormality of sinus node function has been suggested, as evidenced by a higher intrinsic heart rate (after muscarinic and beta-receptor blockade) than that found in normal controls or a blunted response to adenosine with less sinus CL prolongation than in control subjects (with and without autonomic blockade). In addition, β -adrenergic receptor hypersensitivity, α -adrenergic receptor hyposensitivity, M_2 muscarinic receptor hyposensitivity, brain stem dysregulation, depressed efferent cardiovascular reflex, central and peripheral nociceptive effects, hypothalamic paraventricular nucleus stimulation, and impaired baroreflex control have been offered as likely explanations. Chronic beta-receptor stimulation by autoantibodies and autonomic neuritis or autonomic neuropathy can play a role in some cases. The extent to which each of these mechanisms contributes to tachycardia

and associated symptoms is unknown, but the underlying mechanisms are likely multifactorial and complex.^{12,14,15}

Recently, IST has been linked to sinus node channelopathy. A gain-of-function mutation in the *HCN4* gene (which encodes the protein that contributes to formation of *I_f* channels) has been identified in a cohort of patients with IST. HCN mutations can be associated with IST through increased sensitivity to cyclic adenosine monophosphate-dependent activation.^{10,16}

In some patients, there can be an overlap between IST and disorders, such as chronic fatigue syndrome and neurocardiogenic syncope, and other patients can have a psychological component of hypersensitivity to somatic input. Other groups with similar or overlapping laboratory findings and clinical course include patients with hyperadrenergic syndrome, idiopathic hypovolemia, orthostatic hypotension, and mitral valve prolapse syndrome. It is possible that the phenotype of IST is the result of a number of unrelated disorders (much like ventricular tachycardia is the phenotype of many unrelated causes).

EPIDEMIOLOGY AND NATURAL HISTORY

The vast majority of patients afflicted with IST are young women (mean age, 38 ± 12 years), although IST has also been identified in older individuals. IST affects people working in health care in disproportionate numbers, for unknown reasons. The prevalence of IST (symptomatic or asymptomatic) in a middle-aged population (up to 1.2% in one report) appears to be higher than previously assumed.¹⁷

Despite the chronic nature of the disorder and long-lasting symptoms, the natural course and prognosis of IST are generally benign. IST rarely is associated with tachycardia-induced cardiomyopathy, perhaps due to the frequently observed nocturnal slowing of the heart rate.¹²

CLINICAL PRESENTATION

The clinical presentation of the arrhythmia is highly variable, ranging from totally asymptomatic patients identified during routine medical examination to those with short, paroxysmal episodes of palpitations to individuals with chronic, incessant, and incapacitating symptoms. The most prominent symptoms are palpitations, fatigue, and exercise intolerance. IST can also be associated with a host of other symptoms, including chest discomfort, dyspnea, orthostatic intolerance, lightheadedness, dizziness, presyncope, and syncope. Symptoms can start abruptly or insidiously, but typically persist for months or years. Importantly, symptoms may not consistently correlate with periods of tachycardia or can be disproportionate to the severity of the tachycardia. In fact, successful treatment of the tachycardia may not lead to improvement of symptoms. Associated psychiatric conditions are not infrequent, but their relationship to IST is uncertain.^{11,12,18}

INITIAL EVALUATION

IST is an ill-defined clinical syndrome with diverse clinical manifestations. There is no gold standard to make a definitive diagnosis of IST, and the diagnosis remains a clinical one, after exclusion of other causes of symptomatic tachycardia. Clinical examination and routine investigations allow the elimination of secondary causes for the tachycardia but are generally not helpful in establishing the diagnosis of IST.

A thorough history and physical examination is essential to exclude specific physiological, psychological, and pathological causes of appropriate sinus tachycardia (Box 16.1). Blood pressure and heart rate need to be taken in the supine, sitting, immediate standing, and at 2- and 5-minute intervals. Depending on the clinical context, additional work-up can include echocardiography, complete blood count, thyroid function

AF, Atrial fibrillation; SVT, supraventricular tachycardia.

BOX 16.2 Characteristics of Inappropriate Sinus Tachycardia	
Daytime resting sinus rate ≥100 beats/min	
Mean 24-h sinus rate ≥90 to 95 beats/min	
Exaggerated heart rate response to minimal physical or emotional stress	
P wave morphology similar to normal sinus rhythm	
Markedly distressing symptoms	
Lack of secondary causes of sinus tachycardia	

tests, fasting blood sugar, urinary metanephrines, or 24-hour urinary sodium excretion. Evaluation for occult drug abuse (urine and blood drug screening) and psychiatric conditions also need to be considered.

The syndrome of IST is characterized by the following: (1) a relative or absolute increase in sinus rate out of proportion to the physiological demand (a daytime resting sinus rate of more than 100 beats/min, with a mean heart rate more than 90 to 95 beats/min on 24-hour Holter monitor, or an exaggerated heart rate response to minimal physical or emotional stress); (2) P wave axis and morphology during tachycardia that are similar to those noted during normal sinus rhythm; (3) lack of secondary causes of sinus tachycardia; and (4) markedly distressing symptoms of palpitations, fatigue, dyspnea, and anxiety during tachycardia, with an absence of symptoms during normal sinus rates (Box 16.2).

Holter Monitoring

Ambulatory Holter recordings characteristically demonstrate a mean heart rate of more than 90 to 95 beats/min (Fig. 16.1). However, some patients have either a physiological or normal sinus rate at rest (less than 85 beats/min) with an inappropriate tachycardia response to a minimal physiological challenge or a moderately elevated resting heart rate (more than 85 beats/min) with an accentuated (inappropriate)

Fig. 16.1 A 24-Hour Trend of the Long-Term Electrocardiogram Showing Inappropriate Sinus Tachycardia Throughout Usual Activity and on Awakening.

heart rate response to minimal exertion. Importantly, this quantitative definition of ‘inappropriate’ is arbitrary, and validation of the reproducibility of the heart rate and activity correlation can be challenging.^{12,17,18}

Exercise Testing

Exercise electrocardiogram testing typically shows an early and excessive increase of heart rate in response to minimal exercise (heart rate greater than 130 beats/min within 90 seconds of exercise; Bruce protocol), with a maximal heart rate achieved rapidly. This heart rate response is differentiated from physical deconditioning by chronicity and the presence of associated symptoms.

Isoproterenol Provocation

Isoproterenol provocation helps demonstrate sinus node hypersensitivity to β -adrenergic stimulation. Isoproterenol is administered as escalating IV boluses at 1-minute intervals, starting at 0.25 μ g, with doubling of the dose every minute, until a target heart rate increase of 35 beats/min higher than baseline or a maximum heart rate of 150 beats/min is reached. In patients with IST, the target heart rate is reached with an isoproterenol dose of $0.29 \pm 0.1 \mu$ g (vs. $1.27 \pm 0.4 \mu$ g in normal controls).

Autonomic Evaluation

Evaluation of autonomic cardiovascular reflexes can include assessment of intrinsic heart rates, heart rate variation in response to deep breathing, standing and Valsalva maneuver, baroreflex sensitivity, the cardiovagal response (measured by the cold-face test), as well as blood pressure responses to standing and sustained handgrip. Frequently, IST is associated with marked impairment of baroreflex sensitivity (a measure of vagal reflex activity) at rest and during orthostatic stress, suggesting abnormal function of the efferent parasympathetic pathway. IST patients are less responsive to the cold face test (a modification of the diving reflex), demonstrating a substantial incapacity of the heart rate to decrease. However, the clinical value of such tests is questionable and, hence, their routine use is not recommended.^{11,19–21}

Electrophysiological Testing

Invasive electrophysiological (EP) testing can be considered when other arrhythmias are suspected or when a decision to proceed with catheter ablation is undertaken. It is important to recognize that sinus node modification to target IST is a clinical decision, and it must be

made prior to the invasive EP study itself. The diagnosis of IST and the treatment approach should be established before the patient is brought to the EP laboratory.

DIFFERENTIAL DIAGNOSIS

Postural Orthostatic Tachycardia Syndrome

Postural orthostatic tachycardia syndrome (POTS) is a multisystem disorder of the autonomic nervous system, associated with an abnormal response to standing. POTS is characterized by the presence of symptoms of orthostatic intolerance (i.e., the provocation of symptoms on standing that are relieved by recumbence) associated with an exaggerated heart rate increase (30 beats/min or more, or an absolute sinus rate exceeding 120 beats/min) when moving from a recumbent to a standing position held for more than 30 seconds in the absence of orthostatic hypotension (defined as greater than 20 mm Hg drop in systolic blood pressure). For teenagers (12 to 19 years), the required rate increment is at least 40 beats/min.^{11,12}

POTS typically manifests with symptoms of cerebral hypoperfusion (e.g., lightheadedness, presyncope, visual disturbances, cognitive impairment, mental clouding) and excessive sympathetic hyperactivity (e.g., palpitations, chest pain, anxiety, tremulousness), which can cause substantial functional disability. Only a minority of patients with POTS report frank syncope. Importantly, chronic debilitating conditions (e.g., prolonged bed rest), the use of medications known to diminish vascular or autonomic tone, and disorders that might cause tachycardia (e.g., dehydration, anemia) need to be excluded before the diagnosis of POTS is made.²²

The pathophysiological mechanisms of orthostatic intolerance in POTS are heterogeneous and include impaired regulation of peripheral vascular resistance, hyperadrenergic responses, chronic hypovolemia, and deconditioning. Patients with POTS often have high levels of upright plasma norepinephrine, and many patients have a low blood volume.²³

POTS has been classified into several subtypes, including neuropathic and hyperadrenergic POTS. ‘Neuropathic POTS’ is likely caused by primary partial dysautonomia (likely related to an autoimmune process) or peripheral autonomic denervation secondary to other diseases (e.g., diabetes, multiple sclerosis, amyloidosis, sarcoidosis, systemic lupus, alcohol, chemotherapy). In this form, peripheral vasoconstriction in response to orthostatic stress is impaired due to peripheral autonomic neuropathy, resulting in excessive peripheral venous pooling in the lower extremities and mesenteric vasculature and a state of

TABLE 16.1 Inappropriate Sinus Tachycardia Versus Postural Orthostatic Tachycardia Syndrome

	IST	POTS
Definition	HR >100 beats/min at rest (with a mean 24-h HR >90 beats/min not due to primary causes) associated with distressing symptoms	HR increase of >30 beats/min (or an absolute HR >120 beats/min) that occurs within the first 10 min of standing or upright tilt in the absence of orthostatic hypotension, associated with distressing symptoms
HR response to postural change	Increase, but less pronounced than that in POTS. Also, the increase in HR in IST occurs immediately upon standing, unlike POTS.	Profound HR increase (≥ 30 beats/min)
Trigger of tachycardia	Tachycardia is induced by both physiological and emotional stresses without regard to body position	Tachycardia is generally induced only by orthostatic stress
Resting HR in the supine position	Frequently higher than 100 beats/min	Usually within normal range, and rarely exceed 100 beats/min
Response of norepinephrine plasma levels to postural change	Generally, no exaggerated change in norepinephrine levels	Norepinephrine levels increase to ≥ 600 pg/mL is suggestive of hyperadrenergic POTS

HR, Heart rate; IST, inappropriate sinus tachycardia; POTS, postural orthostatic tachycardia syndrome.

“functional” hypovolemia (i.e., low central blood volume) and cerebral hypoperfusion. This, in turn, triggers a sympathetic reflex causing a compensatory increase in both heart rate and myocardial contractility. “Hyperadrenergic POTS” is associated with excessive sympathetic discharge, which can be primary (e.g., norepinephrine reuptake transporter deficiency secondary to genetic mutations), or secondary (precipitated by hypovolemia or drugs). Most patient with hyperadrenergic POTS display exaggerated response to isoproterenol infusion and extremely high plasma levels of norepinephrine (greater than 600 ng/mL) during upright posture.^{11,20,24}

IST shares several characteristics with POTS. Both IST and POTS appear to have abnormal autonomic modulation, associated with exaggerated sinus rate response to orthostatic stress and a multitude of cardiac and noncardiac symptoms that can be debilitating. In addition, both syndromes occur predominantly in young women. Nonetheless, important differences exist between the two conditions (Table 16.1), and the distinction between IST and POTS is important since IST treatments (including catheter ablation of the sinus node) rarely improve, and can even worsen, symptoms in patients with POTS. On the other hand, treatments for POTS can be useless for IST.^{11,12} If orthostatic vital signs are normal and the clinical suspicion of POTS is high, a tilt-table test might be helpful because it can provide vital signs over more prolonged periods than a simple stand test.²⁰

Supraventricular Tachycardia

Supraventricular tachycardias (SVTs), especially sinus nodal reentry or ectopic atrial tachycardias arising at the vicinity of the sinus node, can potentially mimic IST. In addition, IST has been observed following catheter ablation of SVT, in particular following ablation in the Koch’s triangle area (slow and fast pathways of atrioventricular node [AVN], or bypass tracts), which is suspected to result from autonomic dysfunction after ablation and loss of parasympathetic regulation. Therefore careful evaluation is warranted to distinguish the cause of palpitations following an ablation procedure (IST vs. recurrent SVT).²⁵ Fortunately, the post-ablation form of the disorder tends to be transient, with symptoms dissipating within 3 to 4 months post-ablation in the majority of patients.

SVTs typically present with paroxysmal episodes of tachycardia characterized by sudden onset and termination. Warm up and cool down over a few beats also can be observed, especially during automatic atrial tachycardias (ATs). In contrast, IST is nonparoxysmal and is

characterized by more gradual increase and gradual decrease in heart rate with changes in autonomic tone or at the initiation and termination of the tachycardia, respectively.

Adenosine and vagal maneuvers result in either no effect or abrupt termination of SVT, as opposed to gradual slowing of IST. However, automatic ATs can respond to these interventions with transient slowing of the tachycardia rate followed gradual resumption of the AT rate.

Incessant AT can present a diagnostic challenge. Those ATs can be sustained for hours or days, and the tachycardia rate can vary with variations in the level of autonomic tone. Nonetheless, the tachycardia rate typically remains elevated, even during sleep. IST, in contrast, displays more pronounced nocturnal rate variability. Also, incessant ATs usually arise from foci away from the sinus node (most commonly form the atrial appendages and pulmonary veins); therefore the tachycardia P wave usually has a markedly different morphology from the sinus P wave, which facilitates the diagnosis. Furthermore, while SVTs can be associated with long or short RP intervals, IST is invariably associated with long RP intervals (i.e., RP interval longer than PR interval). If SVTs are suspected, an EP study may be considered.

PRINCIPLES OF MANAGEMENT

Conservative medical management with a multidisciplinary approach is the mainstay of therapy for patients with IST. Significant care and attention, effective communication, and patient education are fundamental aspects in management. It is also important to remain empathetic to patients’ complaints and avoid dismissal and minimization of the impact IST can have on the patient’s quality of life.¹¹

Patients will likely benefit by understanding of the basic pathophysiology, natural history, and prognosis of IST. Also, patients should be informed about the expected success and the potential side effects of the various treatment strategies currently available. Patients should be encouraged and empowered to participate in the decision-making process.

Lifestyle changes are beneficial, including avoiding stimulants (drugs, alcohol, and caffeine) and preserving consistent sleep patterns. Exercise training, especially coupled with beta-blocker therapy, can potentially improve quality of life, although the benefit remains unproven.^{11,13}

Pharmacological Therapy

Currently, treatment of IST is generally palliative and directed at controlling symptoms. Heart rate reduction is a goal for most treatment

strategies; however, controlling the heart rate may not alleviate symptoms. Beta-blockers are prescribed as first-line therapy for most patients. Nondihydropyridine calcium channel blockers (verapamil and diltiazem) are acceptable alternatives when beta-blockers are ineffective or not tolerated. Small dosages of benzodiazepines and beta-blocker combinations may also be considered. However, all these regimens have been limited by poor long-term tolerance to the drugs, disappointing long-term clinical response, and lack of strong evidence for benefit.^{11–13}

Ivabradine is a novel selective inhibitor of cardiac pacemaker ion current (I_f), which is highly expressed in the sinus node and contributes to sinus node automaticity. Ivabradine selectivity induces heart rate reduction without any modification in cardiac contractility, or atrioventricular and intraventricular conduction times. Blockade of the I_f current induced by ivabradine is dose and heart rate dependent, resulting in greater effects during fast heart rates and limiting the risk of symptomatic bradycardia. Clinical trials have demonstrated ivabradine to be an effective anti-anginal agent in patients with ischemic heart disease and to offer significant hemodynamic benefits in patients with systolic heart failure and higher baseline heart rates. Several smaller studies also suggest that ivabradine lowers the mean daily and maximal heart rates in patients with IST, improves symptoms, enhances exercise-stress tolerance, and markedly improves quality of life. Ivabradine may be considered a second-line therapy in patients refractory to or intolerant of beta-blockers and nondihydropyridine calcium channel blockers. Ivabradine can also provide benefits when added to beta-blocker therapy. However, large-cohort studies are needed to confirm these results, and long-term safety and efficacy of ivabradine are still to be evaluated.^{13,25–27}

Treatments targeting volume expansion (e.g., generous salt and fluid intake, fludrocortisone, erythropoietin), sympatholytic agents (clonidine, reserpine), cholinesterase inhibitors (pyridostigmine), and phenobarbital have been suggested, but clinical experience is very limited.^{11,12,28} Inconsistent responses to various therapies may suggest that different root causes produce a common apparent phenotype (IST).

Catheter Ablation

Sinus node modification by catheter ablation remains a potentially important therapeutic option in the most refractory cases of IST. Despite high acute procedural success rates (76% to 100%) in reducing sinus rates, the long-term clinical success of catheter ablation for IST remains low (recurrence of symptoms in 27% to 45%, in many cases despite successful reduction of rate), and the risk of complications is significant. Therefore the procedure should be considered as a last resort treatment and only for highly selected patients with debilitating symptoms that are directly related to sinus tachycardia, who have failed lifestyle modifications and all pharmacological treatments, and who have no evidence of other autonomic abnormalities (e.g., POTS).^{11,12,13}

Importantly, if symptoms (especially palpitations) persist despite adequate rate control achieved with medications, sinus node modification would not be expected to offer additional benefit. Furthermore, catheter ablation of the sinus node can result in devastating hemodynamic effects in patients with POTS. Sinus node modification can eliminate the “appropriate” reflex sinus tachycardia needed to overcome the abnormal orthostatic changes (inappropriate vasodilation or inadequate vasoconstriction) in these patients, which can lead to significant hypotension. Therefore the accurate distinction between IST and POTS is extremely important before considering sinus node modification procedures.

Because of the possibility of unsatisfactory results of ablation, it is important to have an understanding with the patient and family about likely outcomes and implications (needing a pacemaker or repeat ablation procedure, persistence of symptoms despite good heart rate control) prior to an ablation procedure.¹³

Surgical Ablation

Multiple surgical techniques have been described for the treatment of IST. Traditionally, surgical ablation of the sinus node is performed through a median sternotomy and cardiopulmonary bypass approach. The procedure is also performed using a thoracoscopic approach or through a mini thoracotomy. Both the traditional and minimally invasive techniques have been associated with limited clinical efficacy and high risk of symptomatic bradycardia requiring permanent pacing therapy. Hence, these treatment approaches are not considered except for the extreme cases and only after all other therapeutic options have been exhausted.^{29,30}

ELECTROPHYSIOLOGICAL TESTING

The goals of EP testing in patients with IST are to exclude other tachycardias that can mimic sinus tachycardia, such as AT originating near the superior aspect of the crista terminalis or right superior pulmonary vein, and to ensure that the tachycardia occurring spontaneously or with isoproterenol infusion acts in a manner consistent with an exaggeration of normal sinus node physiology.

Sedation during procedures is problematic; excessive sedation can potentially impede the ability to initiate other SVTs that mimic IST, as well as creating uncertainty as to what the endpoint heart rate should be after sinus node modification (see later); on the other hand, these procedures can last several hours during which significant patient movement (if not sedated) can potentially invalidate extensive and detailed mapping. Most operators use some form of sedation during these procedures.

For activation mapping, a multipolar (20-pole) crista catheter is placed along the crista terminalis in addition to the catheters used for a routine EP evaluation (coronary sinus, His bundle, and right ventricle [RV]). The crista catheter is positioned on the crista terminalis from the superomedial aspect originating at the junction of the SVC and RA appendage, with continuation along the crista toward the junction of the IVC and RA inferolaterally. Catheter contact with the crista terminalis can be enhanced by using a long sheath (Fig. 16.2). Intracardiac echocardiography (ICE) also may be used to identify the crista terminalis and guide mapping catheter positioning as well as radiofrequency (RF) ablation (see later).

Induction of Tachycardia

Programmed electrical stimulation is performed before and after isoproterenol infusion. Isoproterenol infusion is started at 0.5 to 1.0 $\mu\text{g}/\text{min}$ and titrated every 3 to 5 minutes to a maximum of 6 $\mu\text{g}/\text{min}$. Atropine (1 mg) can also be administered to assess the maximum sinus rate.

It is important to document failure to induce AT and other SVTs during programmed stimulation. IST cannot be initiated with atrial rapid pacing or extrastimulation, but it can be induced by adrenergic stimulation. Initiation of IST is associated with a gradual increase of the sinus rate, with a gradual shift of the earliest atrial activation site up the crista terminalis.

The relevance of EP phenomena, such as dual AVN physiology or AVN echo beats, should be cautiously evaluated in patients in whom the only documented symptomatic tachycardia appears to have a sinus mechanism. Targeting these bystander substrates by catheter ablation can be associated with significant risks and no clinical benefit.

Tachycardia Features

The atrial activation sequence during IST is characterized by a cranio-caudal activation sequence along the crista, with the site of earliest atrial

Fig. 16.2 Catheter Ablation of Inappropriate Sinus Tachycardia. Right anterior oblique (RAO) and left anterior oblique (LAO) fluoroscopic view during sinus node modification. Multipolar (crista) catheter is placed along the crista terminalis with intracardiac echocardiography (ICE) guidance. Abl, Ablation catheter; CS, coronary sinus.

activation shifting up the crista at faster rates and down the crista at slower rates. The earliest atrial activation site always occurs along the crista terminalis (as confirmed by the multipolar catheter placed on the crista) despite a changing tachycardia rate or autonomic modulation (isoproterenol and atropine).

In contrast to focal AT, IST is characterized by a gradual increase and decrease in heart rate with changes in autonomic tone or at the initiation and termination of the tachycardia. In addition, adrenergic stimulation reproducibly causes an increase in IST rate and a cranial shift in atrial activation along the crista terminalis, whereas vagal stimulation causes slowing of the IST rate with caudal shift.

Exclusion of Other Arrhythmia Mechanisms

Several clues can help distinguish sinus tachycardia from sinus node reentrant tachycardia and focal AT. Sinus node reentry is easily and reproducibly initiated with atrial extrastimulation (AES), and AT can be initiated with AES, burst pacing, or adrenergic stimulation. In contrast, IST cannot be initiated with programmed electrical stimulation. In addition, initiation of AT and sinus node reentrant tachycardia is accompanied by a sudden change in atrial rate (although AT can then warm up over a few beats), as opposed to the gradual increase of the IST rate over seconds to minutes. Furthermore, the atrial activation sequence shifts suddenly at the onset of AT or sinus node reentrant tachycardia, as opposed to a gradual cranial shift of the earliest atrial activation up the crista terminalis with adrenergic stimulation as the sinus rate increases during IST. Although the rate of focal AT can continue to increase with continued adrenergic stimulation, this is not associated with a further shift in the atrial activation sequence.

Sinus node reentry is easily and reproducibly terminated with programmed stimulation, whereas IST cannot be terminated with programmed stimulation. The termination of focal AT and sinus node reentry is sudden, as opposed to gradual slowing (cool-down) of the IST rate (Fig. 16.3). Vagal maneuvers result in abrupt termination of sinus node reentry and in either no effect or abrupt termination of AT, while a gradual slowing and inferior shift down the crista terminalis of the site of origin characterizes IST. Abrupt termination of the tachycardia

with a single RF application suggests AT because IST originates from a widespread area involving the superior crista terminalis.

ABLATION

Target of Ablation

Understanding the anatomy and physiology of the sinus node (see Chapter 8) is critical for identifying the target of ablation for sinus node modification. The sinus node region is a distributed complex characterized by rate-dependent site differentiation (i.e., there is anatomical distribution of impulse generation with changes in sinus rate), which allows for targeted ablation to eliminate the fastest sinus rates while maintaining some degree of sinus node function.

Sinus node modification targets the site of most rapid discharge, generally at the superior aspect of the crista terminalis. One must recognize, however, that sinus node modification is not a focal ablation, but requires complete abolition of the cranial portion of the sinus node complex (eFig. 16.1). Ideally, this procedure eliminates the areas of the sinus node responsible for rapid rates while preserving some chronotropic competence.

Of note, while the head and proximal body portion of the sinus node usually are located subepicardially, lying 0.1 to 1.0 mm beneath the fatty tissue of the sulcus terminalis on the epicardial surface, the remaining nodal body and tail portions penetrate inferiorly and obliquely into the musculature of crista terminalis to end subendocardially almost to the IVC. This is relevant to the ablation procedure, since the superior portion of the sinus node (which constitutes the target of ablation) can be more difficult to ablate with endocardial catheter techniques. On the other hand, the inferior portion of the sinus node, which is to be preserved, is likely to be more vulnerable to endocardial ablation.³

Ablation Technique

The crista terminalis is not visible on fluoroscopy and has a varied course among patients. Therefore some operators prefer using ICE to help identify the crista, position the tip of the ablation catheter with firm contact on the crista, and assess the RF lesion (see eFig. 11.9). A

eFig. 16.1 Integrated computed tomography (CT) and electroanatomic (CARTO) map of the right atrium acquired during sinus node modification. Right anterior oblique and cardioscopic views of the CT scan are shown. Note the area targeted by radiofrequency ablation (*red dots*) starting cranially at the medial portion of the crista as it courses in front of the superior vena cava (SVC). RAA, Right atrial appendage.

Fig. 16.3 Focal Atrial Tachycardia. A 12-lead electrocardiogram showing perinodal focal atrial tachycardia (or sinus node reentrant tachycardia) with abrupt termination and restoration of normal sinus rhythm. Note the similarities between the tachycardia and sinus P wave morphology.

3-D contact mapping system (CARTO, NavX, Rhythmia) or noncontact mapping can also help delineate relevant anatomical structures (SVC, boundaries of atrium), define the extent of the earliest site of activation during IST, delineate the course of the phrenic nerve (sites at which pacing stimulates the diaphragm), and catalog the sites of ablation (Fig. 16.4).^{31,32} Some operators define the site of earliest activation during the resting baseline rhythm and tag this region as one to hopefully avoid during subsequent ablation (eFig. 16.2).

A multipolar catheter is placed along the crista terminalis (with or without ICE guidance). A standard ablation catheter with a 4- or 8-mm-tip or an irrigated-tip catheter is used for RF application. For nonirrigated ablation, RF power is adjusted to achieve a tip temperature of 50°C to 60°C or an impedance drop of 5 to 10 Ω , or both. For irrigated ablation, RF power up to 40 to 50 W may be considered, keeping the tip temperature less than 43°C.³³

RF lesions are applied as guided by the earliest atrial activation time, usually along superior regions of the crista terminalis using the guidance of the crista catheter. The local endocardial activation time recorded by the ablation catheter at successful sites typically precedes the onset of the surface P wave during the tachycardia by 25 to 45 milliseconds (Fig. 16.5).

RF ablation is performed under maximal adrenergic stimulation with isoproterenol (with or without parasympathetic blockade with atropine) to reveal the superior portions of the crista terminalis as the earliest sites of atrial activation. The medial portion of the crista as it courses in front of the SVC is usually the site of earliest activation for the fastest sinus rates; this portion of the crista should be targeted by RF ablation first. Progressively inferior portions of the crista are then ablated until the target heart rate reduction is achieved. Whenever a sustained change in sinus rate or P wave axis is observed, activation mapping is repeated to identify the new sites with the earliest atrial

activation to target with ablation (see Fig. 16.4). This technique often requires ablating an estimated area of $12 \pm 4 \times 19 \pm 5$ mm.

RF energy delivery at any one site should probably be limited to 30 seconds because these are usually closely spaced applications, which carry the risk of char formation with longer applications. Pacing from the ablation catheter tip at high output (5 to 10 mA) is necessary before each RF application to verify the absence of diaphragmatic stimulation to avoid phrenic nerve injury.

Acceleration of the sinus rate followed by a marked subsequent rate reduction or the appearance of a junctional rhythm during ablation is an indicator of a successful ablation site. Most patients demonstrate a stepwise reduction in sinus rate during the course of ablation, which is associated with migration of the site of earliest atrial activation in a craniocaudal direction along the crista terminalis (see Fig. 16.5). However, it is not uncommon to observe an abrupt reduction in the sinus rate in response to RF ablation at a focal site of earliest atrial activation (Fig. 16.6). Echocardiographic lesion characteristics using ICE can also provide a guide for directing additional RF lesions. The effective RF lesion has an increased or changed echodensity completely extending to the epicardium with the development of a trivial linear low-echodensity or echo-free interstitial space, which suggests a transmural RF lesion.³³

Feasibility of the epicardial ablation (via the subxiphoid pericardial approach) for sinus node modification has been recently demonstrated in a small series. Epicardial access can also help reduce the risk of phrenic nerve injury during endocardial ablation. Instilling saline or placing a deflectable electrode catheter in the pericardial space can help physically displace the phrenic nerve from the ablation zone (eFig. 16.3).^{34,35}

Endpoints of Ablation

Acute procedural success is defined as: (1) abrupt reduction of the sinus rate by 30 beats/min or more during RF delivery or a 20% to 25%

eFig. 16.2 Use of isoproterenol to “force” site of impulse formation to more cephalad portion of sinus node. (A) Baseline electroanatomic activation map of sinus rhythm showing a site (*red*) at the junction of the superior vena cava (SVC) and right atrial body. (B) After isoproterenol administration, the site of earliest activation has moved closer to the SVC. Black dots are sites of phrenic nerve capture. CS, Coronary sinus; IVC, inferior vena cava; TA, tricuspid annulus.

(C and D) Fluoroscopic views of catheters during sinus node modification. A deflectable quadripolar electrode catheter (*Peric. Cath.*) has been introduced through a sheath in the pericardium (*Peric. Sheath*) to physically displace the right phrenic nerve and enable safe ablation of the sinus node region from an endocardial approach. A and C are shown in right anterior oblique projection. B and D are shown in left anterior oblique projection. CS, Coronary sinus catheter.

Fig. 16.4 Electroanatomic Map of Inappropriate Sinus Tachycardia. (A) Right anterior oblique view of the right atrium showing electroanatomic (CARTO) activation map of inappropriate sinus tachycardia. White dots indicate course of phrenic nerve capture during high-output pacing; red dots indicate ablation lesions. (B to D) Successful ablation with repeat activation mapping showing shifts of the site of origin of the sinus P wave from the superior aspect of the crista terminalis (B) at baseline to progressive more caudal sites (C and D) along the crista as a result of ablation of sinus node modification. (Modified from Peyrol M, Lévy S. Clinical presentation of inappropriate sinus tachycardia and differential diagnosis. *J Interv Card Electrophysiol.* 2015;46:33–41.)

Fig. 16.5 Intracardiac Recordings During Sinus Node Modification. *Left panel*, Before ablation (ABL) and under adrenergic stimulation, sinus tachycardia is observed, with the earliest local activation (red arrows) recorded by the most distal (cranial) electrodes of the crista catheter, just anterior to the superior vena cava-right atrial junction. Note that local activation recorded by the ablation catheter (blue arrow) precedes the onset of the P wave (indicated by the vertical dashed line) by 20 to 30 milliseconds. *Middle panel*, Following ablation of the most cranial part of the sinus node, the sinus rate becomes slower, and the activation sequence shifts toward more proximal (caudal) electrodes 7 to 8 on the crista catheter. *Right panel*, Following successful sinus node modification, the sinus rate (under constant adrenergic stimulation) is reduced by more than 30%, and the atrial activation sequence shifts to the most proximal (caudal) crista catheter electrodes. Note the P wave is now inverted in lead II. *dist*, Distal; *prox*, proximal.

Fig. 16.6 Sinus Node Modification. An abrupt reduction in the sinus rate is observed in response to radio-frequency (RF) ablation (ABL) at a focal site of earliest atrial activation. *dist*, Distal; *prox*, proximal.

decline in maximum heart rate (or an absolute sinus rate of less than 120 beats/min) during infused isoproterenol and atropine; (2) persistent reduction of the resting sinus rate by 10% or more (or an absolute resting sinus rate of less than 90 beats/min); (3) maintenance of a superiorly directed P wave (negative P wave in lead III); and (4) inferior shift of the site of earliest atrial activation down the crista terminalis, even with maximal adrenergic stimulation.³³

RF ablation of IST often is difficult and requires multiple RF applications; a mean of 12 RF applications (range, 6 to 92) was required in one study. The resilience of the sinus node to endocardial catheter ablation can be explained, in part, by the architectural features of the node—the dense matrix of connective tissue in which the specialized sinus node cells are packed; the cooling effect of the nodal artery; the subepicardial nodal location; and the thick terminal crest, particularly in relation to the nodal portion caudal to the sinus node artery. In addition, the length of the sinus node, the absence of an insulating sheath, the presence of nodal radiations, and caudal fragments offer a potential for multiple breakthroughs of the nodal wavefront.³³

Outcome

Prior to undertaking ablation of the sinus node for IST, both the physician and the patient should have realistic expectations and understanding of the goals of ablation and potential outcomes. Relatively few patients will achieve the desired combination of relief of symptoms and normal resting heart rate and chronotropic response without the need for implantation of a permanent pacemaker. In some patients, symptoms persist despite successful EP endpoints of the ablation procedure. In others, IST is replaced by an equally (or even more) bothersome accelerated junctional rhythm at 80 to 90 beats/min with retrograde conduction. In these patients, a generalized dysautonomia can potentially be the underlying cause.

RF ablation is, at best, only modestly effective for managing patients with IST. Although short-term success rates can be favorable (76% to 100%), long-term outcomes are disappointing, with clinical success rates ranging between 23% and 83%. Complete ablation of the sinus node (targeting the entire crista terminalis) resulting in junctional rhythm has better long-term success (72%) but requires pacemaker insertion.^{33,36}

Most recurrences occur 1 to 6 months after the procedure and are typically related to tachycardia recurrence after an initially successful procedure. A repeat procedure may be necessary in patients with intolerable symptoms. Symptomatic recurrence or persistence of symptoms in the absence of documented IST and despite persisting evidence of a successful EP outcome has been observed in some cases. Persistent symptoms, despite heart rate reduction, may be suggestive of a more global dysautonomia that also happens to affect the sinus node.^{33,12}

Complications of sinus node modification include cardiac tamponade, SVC syndrome, diaphragmatic paralysis, and sinus node dysfunction. Cardiac tamponade is rare and usually is caused by penetration of an unattended RV catheter in a thin female patient with rapid and vigorous heart action because of high-dose isoproterenol infusion. Transient SVC syndrome can develop because of extensive lesion creation and edema at the SVC-RA junction. This can rarely cause permanent SVC stenosis. More targeted ablation using ICE may help avoid this complication.

Diaphragmatic paralysis secondary to damage to the right phrenic nerve should be minimized if ablative lesions are confined to the crista itself or placed just anterior to it. Using ICE to guide ablation makes this complication unlikely because the phrenic nerve is a posterior structure. Pacing with a high output (greater than 10 mA at 2 milliseconds) from the ablation catheter at the target site without capture of the phrenic nerve and continuous pacing higher in the SVC to capture the phrenic nerve during RF ablation are reassuring, but their efficacy

has never been assessed; in fact, there have been cases in which phrenic palsy developed several days after ablation despite taking all the above precautions. In addition, suspicion of phrenic nerve injury should be considered in the case of hiccup, cough, or a decrease in diaphragmatic excursion during energy delivery. Early recognition of phrenic nerve injury during RF delivery allows the immediate interruption of the energy application prior to the onset of permanent injury and is associated with rapid recovery of phrenic nerve function. If phrenic nerve injury prohibits ablation at desired endocardial sites, displacement of the phrenic nerve from the ablation target site via saline injection or balloon catheter placement in the pericardial space (through the sub-xiphoid approach) can be considered.^{34,35,37} Persistent slow junctional rhythm requiring pacemaker insertion is rare. Such junctional rhythm usually disappears with the return of sinus rhythm within several days.³⁸

ANATOMY AND PHYSIOLOGY OF THE ATRIOVENTRICULAR NODE

The atrioventricular node (AVN) is the only normal electrical connection between the atria and the ventricles; the fibrous skeleton acts as an insulator to prevent electrical impulses from entering the ventricles by any other route. The main function of the AVN is modulation of atrial impulse transmission to the ventricles; it introduces a delay between atrial and ventricular systole, thereby allowing atrial systole and ventricular filling to complete prior to the initiation of ventricular systole.¹ Another primary function of the AVN is to limit the number of impulses conducted from the atria to the ventricles. This function is particularly important during fast atrial rates (e.g., during atrial fibrillation [AF] or atrial flutter [AFL]), in which only a few impulses are conducted to the ventricles, and the remaining impulses are blocked in the AVN (facilitated by the relatively long refractory period of the AVN). In addition, fibers in the lower part of the AVN can exhibit automatic impulse formation, serving as a subsidiary pacemaker.^{2,3}

Triangle of Koch

The triangle of Koch constitutes the endocardial surface of the region of the lower right atrium (RA) septum. It is bordered anteriorly by the insertion of the septal leaflet of the tricuspid valve and posteriorly by the fibrous tendon of Todaro. The apex of the triangle is formed by the junction of these two boundaries. The base of the triangle is formed by the anteromedial edge of the coronary sinus ostium (CS os) and is continuous with the sub-eustachian pouch (Fig. 17.1; see Fig. 9.2, eFig. 12.1).^{2,3}

The tendon of Todaro is a fibrous band that connects to the central fibrous body as a fibrous extension of the membranous septum. It courses obliquely between the fossa ovalis and the CS os, crossing the eustachian ridge in the floor of the RA, and connecting to the valve of the inferior vena cava (IVC) (eustachian valve).⁴

Of note, the interatrial sulcus is displaced to the far left of the inter-ventricular sulcus; the atrioventricular (AV) valves are not isoplanar; and the attachment of the septal leaflet of the tricuspid valve into the most anterior part of the central fibrous body is displaced a few millimeters apically relative to the attachment of the septal leaflet of the mitral valve. Thus the true septal part of the AV junction (the RA–left ventricle [LV] sulcus) actually separates the inferomedial RA from the posterior superior process of the LV (the right side above the tricuspid valve while the left side is below the mitral valve). Hence, the triangle of Koch can be considered the RA side of the AV muscular septum.

The mean distances from the His bundle (HB) electrogram recording site (at the apex of the triangle of Koch) to the upper and lower lips of the CS os are 10 mm (range, 0 to 23 mm), and 20 to 25 mm (range, 9 to 46 mm), respectively. However, it is important to note that electroanatomic mapping studies revealed individual variations in the locations of the HB and slow pathway recording sites as well as anatomic variations in the sizes of the Koch triangle and the CS os. A downward deviation of the HB to the midseptum is not uncommon, especially in older patients. Such a downward deviation of the HB may account for unexpected AV block during slow pathway ablation.⁵

Atrioventricular Node

The AVN is an intraatrial structure, measuring approximately 5 mm long, 5 mm wide, and 0.8 mm thick in adults. The compact node is

Fig. 17.1 Anatomy of the Triangle of Koch. *Left*, The interior of the morphologically right atrium has been revealed by making a cut in the appendage parallel to the atrioventricular groove, and reflecting the wall of the appendage upwards. Note that the pectinate muscles forming the wall of the appendage take their origin from the terminal crest, and sweep round to insert on the posterior septal wall, having passed beneath the mouth of the coronary sinus, this being guarded by the Thebesian valve. *Right*, The important posterior wall of the right atrium has been enlarged. Note the location of the triangle of Koch, delimited by the site of the tendon of Todaro, the attachment of the septal leaflet of the tricuspid valve, and the mouth of the coronary sinus. The small bracket shows the site of the septal isthmus, whereas the large bracket shows the inferior, or cavotricuspid, isthmus. SCV, Superior caval vein. (From Anderson RH, Cook AC. The structure and components of the atrial chambers. *Europace*. 2007;9[Suppl 6]:3–9.)

adjacent to the central fibrous body on one side but is uninsulated by fibrous tissue on its other sides, thus allowing contiguity with the atrial myocardium. The AVN is located beneath the RA endocardium at the apex of the triangle of Koch, anterior to the CS os and directly above the insertion of the septal leaflet of the tricuspid valve, where the tendon of Todaro merges with the central fibrous body. Slightly more anteriorly and superiorly is where the HB penetrates the AV junction through the central fibrous body and the posterior aspect of the membranous AV septum.

When traced inferiorly, toward the base of the triangle of Koch, the compact AVN area separates into two extensions, usually with the artery supplying the AVN running between them. The prongs bifurcate toward the CS os along the tricuspid annulus (right posterior [inferior] extension) and toward the mitral annulus (left posterior [inferior] extension). The right posterior nodal extension and its corresponding atrionodal (AN) approaches have been implicated as the anatomic substrate for the so-called “slow pathway” in the atrioventricular nodal reentrant tachycardia (AVNRT) circuit. The tachycardia circuit also can involve the left posterior nodal extension (see later). The “fast pathway” is less well defined from an anatomic and structural standpoint. The probable anatomic substrate of this pathway consists of the transitional cell layers located around the compact AVN (in the anterior portion of the triangle of Koch) at the interface between the compact node and the transitional cells.^{2,3,6}

Functionally, based on activation times during anterograde and retrograde propagation, and on the action potential characteristics from microelectrode recordings in the rabbit AV junction, the cells of the AVN and perinodal region are frequently described as AN, N (nodal), and NH (nodal-His), with the AN and NH regions more sodium dependent for depolarization, and the N region being calcium dependent, and the likely region where calcium channel blockers act. The transition from one cell area to the other is gradual, with intermediate cells exhibiting intermediate action potentials with great changes related to the autonomic tone.

Atrionodal Region

The AN region corresponds to the cells in the transitional region that are activated shortly after the adjacent atrial cells. Transitional cells are

histologically distinct from both the cells of the compact AVN and the working atrial myocytes, and they are not insulated from the surrounding myocardium, but tend to be separated from one another by thin fibrous strands. Transitional cells do not represent conducting tracts but a bridge funneling atrial depolarization into the compact AVN via discrete AN inputs (approaches). AN approaches connect the working atrial myocardium from the left and right sides of the atrial septum to the left and right margins of the compact node, with wider extensions inferiorly and posteriorly between the compact node and the CS os and into the eustachian ridge. In humans and animals, two such AN inputs are commonly recognized in the right septal region: the anterior (superior) approaches, which travel from the anterior limbus of the fossa ovalis and merge with the AVN closer to the apex of the triangle of Koch; and the posterior (inferior) approaches, which are located in the inferoseptal RA and serve as a bridge with the atrial myocardium at the CS os. Although both inputs have traditionally been assumed to be RA structures, growing evidence supports the AV conduction apparatus as a transeptal structure that reaches both atria. A third, middle group of transitional cells has also been identified to account for the nodal connections with the septum and left atrium (LA).^{2,3}

Nodal Region

The N region corresponds to the region where the transitional cells merge with midnodal cells. The N cells represent the most typical of the nodal cells, which are smaller than atrial myocytes, are closely grouped, and frequently are arranged in an interweaving fashion. Sodium channel density is lower in the midnodal zone of the AVN than in the AN and NH cell zones. The inward L-type calcium current is the basis of the upstroke of the N cell action potential. The N cells are characterized by a less negative resting membrane potential and low action potential amplitude, slow rates of depolarization and repolarization, few intercellular connections (e.g., gap junctions), and reduced excitability compared with surrounding cells. Therefore conduction is slower through the compact AVN than the AN and NH cell zones. In fact, the N cells in the compact AVN appear to be responsible for the major part of AV conduction delay and exhibit decremental properties in response to premature stimulation because of their slow rising and longer action potentials. Fast pathway conduction through the AVN apparently bypasses

many of the N cells by transitional cells, whereas slow pathway conduction traverses the entire compact AVN. Importantly, the recovery of excitability after conduction of an impulse is faster for the slow pathway than for the fast pathway, for reasons that are unclear.¹

Nodal-His Region

The NH region corresponds to the lower nodal cells, typically distal to the site of Wenckebach block, connecting to the insulated penetrating portion of the HB. The action potentials of the NH cells are closer in appearance to the fast-rising and long-action potentials of the HB.

PATHOPHYSIOLOGY

Tachycardia Circuit

The exact electroanatomic circuit responsible for AVNRT remains elusive. Current evidence suggests that dual AVN pathway physiology constitutes the substrate for AVN reentry. The different atrial inputs to the AVN, rather than functional longitudinal dissociation within the compact AVN, represent the fast and slow pathways involved in the reentrant circuit. The right and left inferior extensions of the AVN and their corresponding AN inputs have been implicated as the anatomic substrate for the slow pathway(s) in the AVNRT circuit. However, the fast pathway is less well defined from an anatomic and structural standpoint. The probable anatomic substrate of this pathway consists of the transitional cell layers located around the compact AVN (in the anterior portion of the triangle of Koch) at the interface between the compact node and transitional cells.^{2,3,6-8}

It is important to recognize that dual AVN physiology characterizes the normal AVN electrophysiology, and the presence of dual (or multiple) AVN pathways can be demonstrated in most individuals with or without AVNRT, and is not necessarily indicative of the existence of functional reentry.^{2,3} However, although the potential substrate for AVNRT (dual pathways) is normally available, only a minority of normal individuals develop AVN reentry. This is likely related to the fact that reentry requires several other conditions to be met at the same time, including appropriately timed conduction times and refractoriness over the two pathways as well as the prevalence of perfectly timed triggers (premature atrial complex [PACs] or premature ventricular complex [PVCs]).

The understanding of the AVN as having superior (anterior) and inferior (posterior) right and left inputs that form the fast and slow pathways, respectively, is a simple conceptual framework that seems to enable the clinician to confront most cases. Reentry occurring along these pathways is the basic mechanism for the various subtypes of AVNRT. The proximal atrial insertions of the fast and slow pathways are anatomically distinct during retrograde conduction, and several important functional differences exist between the two pathways.^{2,3,6-8}

Differences Between the Fast and Slow Pathways

The fast and slow pathways exhibit different electrophysiological (EP) properties. In general, the fast pathway demonstrates faster conduction velocity but longer refractory periods than the slow pathway. However, many exceptions exist.⁶

The fast pathway forms the normal physiological conduction axis, and the atrial-His bundle (AH) interval during conduction over the fast pathway is usually no longer than 220 milliseconds. Longer AH intervals can be caused by conduction over the slow pathway.

Furthermore, the AVN dual pathways are greatly influenced by changes in the sympathovagal balance. Sympathetic stimulation shortens conduction time and refractoriness, whereas vagal stimulation provides the opposite effect. However, the relative extent of these effects on the two pathways can be different, which can potentially cause conduction to shift from one pathway to the other. An increase in vagal tone

preferentially prolongs the effective refractory period (ERP) of the fast pathway compared to the slow pathway. Adrenergic stimulation tends to shorten the anterograde and retrograde ERP of the fast pathway to a greater extent than that of the slow pathway. Conversely, beta-blockers tend to prolong ERP of the fast pathway more than that of the slow pathway. Notably, adenosine produces differential effect on anterograde and retrograde conduction over the different AVN pathways. The effect of adenosine seems to be far less potent on retrograde fast pathway conduction than on the retrograde slow pathway and anterograde fast and slow pathway conduction. The mechanism of adenosine resistance of retrograde fast pathway conduction (both in patients with slow-fast AVNRT and in normal subjects) remains unclear.⁹

Investigators used several approaches to identify the location of the atrial input of AVN pathways involved in the AVNRT circuit. The pathway serving as the retrograde limb of an AVNRT circuit can be identified by mapping the site of earliest retrograde atrial activation during AVNRT. The anterograde limb of the AVNRT circuit can be identified by using the resetting response to late-coupled atrial extra-stimulation (AES); the site where the AES (with the longest coupling interval) *resets the tachycardia* identifies the anterograde limb. Atrial entrainment of AVNRT can also identify the anterograde limb of the reentry circuit; the site of the shortest stimulus-to-His interval with a postpacing interval (PPI) equal to the tachycardia cycle length (TCL) identifies the location of the atrial input to the anterograde pathway. Several studies demonstrated that slow pathways with longer conduction times frequently have a more inferior location in the triangle of Koch when compared with locations producing shorter AH intervals. However, atypical locations of those pathways are not infrequent.

Fast Pathway

Typically, a single fast pathway is identified in normal subjects and in patients with AVNRT. During retrograde fast pathway conduction, the earliest retrograde atrial activation is typically recorded at the apex of the triangle of Koch (superior to the compact AVN, at the same site recording the proximal His potential). However, detailed mapping localized the earliest site of atrial activation to the anterior interatrial septum posterior to the tendon of Todaro and eustachian ridge (outside the triangle of Koch, at a level approximately 10 mm inferior to the level recording the proximal HB potential).⁸

Slow Pathways

Data suggest the presence of several slow pathways that can potentially participate in various forms of AVNRT, either as the anterograde or retrograde limbs of the reentry circuit. The slow pathway most commonly incorporated in the AVNRT circuit is formed by the rightward inferior AVN extension (and its corresponding AN approaches), which travels in the triangle of Koch between the tricuspid annulus and the CS os and connects selectively to the floor of the CS os. The earliest atrial activation during retrograde conduction over this pathway is typically located at the inferior aspect of the triangle of Koch, close to the CS os.^{2,3,6} The second most commonly used slow pathway is formed by the leftward inferior AN extension, which travels within the myocardial coat of the proximal CS leftward (transseptally) toward the left inferoseptal region and mitral annulus. An eccentric activation sequence in the CS is observed during retrograde conduction over this pathway, with the earliest activation site at the roof of the proximal CS (1 to 3 cm from the CS os). Two other slow pathways (inferolateral left atrial pathway and anterosseptal pathway) have been described but are less frequently observed. The earliest retrograde atrial activation is located close to the inferolateral mitral annulus in the LA (for the inferolateral left atrial slow pathway) or the anterior atrial septum, close to the proximal HB (for the anterosseptal slow pathway).

Multiple slow pathways (as demonstrated by multiple discontinuities in the AVN function curves; see later) are present in up to 14% of patients with AVNRT, although not all these pathways are involved in the initiation and maintenance of AVNRT. For example, an eccentric CS activation pattern has been reported frequently (14% to 80%) among patients with atypical forms of AVNRT. Whether the retrograde left-sided AN connection constitutes the critical component of the reentrant circuit or is only an innocent bystander in atypical AVNRT with the eccentric CS activation pattern remains controversial. It may be possible for both the leftward and rightward extensions, either together or separately, to participate in AVN reentry. Right-sided ablation is probably sufficient for most of these patients. However, in some patients, the slow pathway participating in the reentrant circuit cannot be ablated from the posteroseptal RA or the CS os, and requires ablation along the roof of the CS, as much as 5 to 6 cm from the CS os, or mitral annulus.

Upper Turnaround Point

Based on rare cases of dissociation of atrial activation from the tachycardia (e.g., persistence of AVNRT during different patterns of ventriculoatrial [VA] block or during AF) and on similarities between fast-slow AV conduction and longitudinal-transverse conduction in nonuniform anisotropy, early studies proposed that AVNRT results from reentry within the compact AVN (i.e., subatrial) secondary to functional longitudinal dissociation within the AVN into fast and slow pathways. Those studies suggested the presence of an upper common pathway, at least in a subset of patients.

However, current evidence, derived from histological studies, computer modeling, multielectrode recordings, and optical mapping, supports the role of perinodal atrial myocardium and suggests that the fast and slow pathways involved in the reentrant circuit of AVNRT represent conduction over different AN connections, thus making at least a small amount of atrial tissue a necessary part of the reentrant circuit (see [Video 17.1](#)). The common presence of multiple atrial breakthroughs, and the frequent changes in timing and location of retrograde activation without significant alteration in AVNRT cycle, argues against the existence of an “upper common pathway” or a focal atrial exit site from the AVNRT circuit in the majority of patients.

Lower Turnaround Point

The AVNRT circuit does not involve the ventricles; however, the location of the lower turnaround point of AVN reentry relative to the HB has been controversial. There is good evidence that the distal junction of the slow and fast pathways is located in the AVN, with the existence of a region of AVN tissue extending between the distal junction of the two pathways and the HB (called the “lower common pathway”), at least in a subset of patients.

The existence of a lower common pathway was proposed to explain several observations, including (1) AV block occurring without interruption of AVNRT and without recording of a His electrogram; (2) ventricular extrastimulation (VES) during AVNRT prematurely depolarizing the HB without affecting the tachycardia; (3) AES during AVNRT resulting in changes in the relative activation of HB and atrium (i.e., varying His bundle-atrial [HA] intervals); and (4) the HA interval during ventricular pacing at the TCL is longer than that during AVNRT.^{10,11}

The HA interval (measured from the end of the His potential to the earliest atrial activation in the HB recording, assuming stable activation sequence) during ventricular pacing represents a true conduction time between the HB and atrium. In the presence of a lower common pathway, the HA interval during AVNRT represents the relative activation times between the HB and junctional atrium, since the reentrant wavefront travels retrogradely up an AVN pathway to activate the atrium,

while at the same time propagating down the lower common pathway to activate the HB (i.e., the HA is a “pseudo-interval”). Consequently, in the presence of a lower common pathway between the AVNRT circuit and HB recording site, the HA during AVNRT is expected to be shorter than that during ventricular pacing. The difference between the two HA intervals (Δ HA interval) is proportional to the length of the lower common pathway.

However, these phenomena can be interpreted in ways that do not involve the presence of a common pathway. For example, the first two phenomena assume that the recorded “proximal HB” potential corresponds to the actual “proximal end of the HB,” which is probably inaccurate in many cases. Hence, those phenomena also can be explained by intra-Hisian block occurring beyond the site of HB recording rather than in a “lower common pathway.”¹⁰ Furthermore, the last two phenomena assume that retrograde conduction follows the same pathway during pacing and tachycardia, and the difference between the HA interval during tachycardia and that during ventricular pacing at the TCL was assumed to reflect the conduction time over the lower common pathway. On the contrary, mapping studies have demonstrated that the breakthrough of atrial activation during AVNRT is frequently slightly discordant from that observed during ventricular pacing. Hence, relying on the measuring the HA interval from the same recording sites, rather than detailed mapping for the true site of “earliest” atrial activation, may not be accurate.¹⁰

Types of Atrioventricular Nodal Reentry

AVNRT can manifest in different forms depending on the anatomic substrate forming the anterograde and retrograde pathways incorporated in the reentry circuit. Traditionally, AVNRT has been classified into “typical” or “atypical” forms. Typical AVNRT (anterograde slow-retrograde fast) accounts for 90% of AVNRTs. Atypical AVNRT variants are traditionally subclassified as either fast-slow or slow-slow types. The distinction between these various forms of AVNRT has been based on: (1) the absolute values of the AH and HA intervals; (2) the AH/HA ratios; (3) the pattern of earliest retrograde atrial activation; and (4) the identification of a lower common pathway ([Table 17.1](#)).

However, this classification approach has several limitations. As noted previously, the methodology for determining the presence or absence of a lower common pathway is not reliable (as discussed above). In addition, retrograde atrial activation over both fast and slow conduction patterns exhibit significant heterogeneity in all forms of AVNRT. Both typical and atypical AVNRT are compatible with varying retrograde atrial activation patterns. Furthermore, the conduction properties of the fast and slow AVN pathways (and thus the absolute and relative values of the AH and HA intervals) depend on the autonomic status, and can change in the same patient during the same EP study in response to changes in the sympathovagal balance.¹⁰

A more simplified and clinically practical scheme was recently proposed, which classifies the different types of AVNRT into only two categories, typical versus atypical, based only on the AH/HA ratio and absolute HA (or VA) intervals, while disregarding the retrograde atrial activation sequence and the demonstration of a lower common pathway ([Table 17.2](#)). Also, both fast-slow and slow-slow atypical AVNRTs were combined together since the distinction between the two types is often arbitrary in view of the lack of a unanimously accepted definition.¹⁰

The HA interval is measured from earliest deflection of the HB activation to the earliest rapid deflection of the atrial activation in the HB electrogram. The VA interval (measured from the onset of ventricular activation on surface electrocardiogram [ECG] to the earliest rapid deflection of the atrial activation on the HB electrogram) is also a practical and easily obtainable criterion, when the His potential cannot be reproducibly and reliably recorded during tachycardia.

TABLE 17.1 Traditional Classification of Atrioventricular Nodal Reentrant Tachycardia Types

	Typical (Slow-Fast)	Atypical (Fast-Slow)	Atypical (Slow-Slow)
AH interval	>200 ms	<200 ms	>200 ms
HA interval	<70 ms	≥70 ms	≥70 ms
AH/HA ratio	>1	<1	≥1
Site of earliest retrograde atrial activation	Apex of the triangle of Koch	CS os or within 1–2 cm of the proximal CS	CS os or within 1–2 cm of the proximal CS
Lower common pathway	Short or absent	Long	Long

AH, Atrial–His bundle; CS os, coronary sinus ostium; HA, His bundle–atrial.

TABLE 17.2 Simplified Classification of Atrioventricular Nodal Reentrant Tachycardia Types

	Typical (Slow-Fast)	Atypical (Fast-Slow or Slow-Slow)
HA interval	≤70 msec	>70 msec
VA interval	≤60 msec	>60 msec
AH/HA ratio	>1	Variable

AH, Atrial–His bundle; HA, His bundle–atrial; VA, ventriculoatrial.

Typical (Slow-Fast) Atrioventricular Nodal Reentrant Tachycardia

Anterograde conduction. The anterograde limb of the reentry circuit is formed by a slow pathway. Mapping studies localized the input to the anterograde slow pathway to the midseptum (in 50%) or inferior septum (33%), and infrequently to the superior septum (13%) or CS (3%).^{8,10,12} Some investigators subdivided typical slow-fast AVNRT according to the putative slow pathway used anterogradely, based on the site of successful ablation. At least three subtypes were described: (1) rightward inferior extension slow-fast AVNRT (most common), which is typically eliminated by ablation at the inferior aspect of the triangle of Koch; (2) leftward inferior extension slow-fast AVNRT (uncommon, 5%), which requires ablation within the triangle of Koch superior to the level of CS os and closer to the compact AVN or at the roof of the proximal CS (1 to 3 cm from the CS os); and (3) inferolateral left atrial slow-fast AVNRT (rare), which requires ablation close to the inferolateral mitral annulus in the LA.

Retrograde conduction. Typical AVNRT uses the fast pathway for retrograde conduction. During slow-fast AVNRT, the earliest retrograde atrial activation is usually recorded at the anterior interatrial septum posterior to the tendon of Todaro, close to the apex of the triangle of Koch (Fig. 17.2).⁸

Importantly, retrograde atrial activation has been mapped to the inferior triangle of Koch, the roof of the CS (1 to 3 cm from the CS os), or the left side of the septum in up to 9% of patients (Fig. 17.3). These forms of AVNRT were considered variants of slow-fast AVNRT with an inferior exit for the retrograde fast pathway. More recently, however, those AVNRTs with earliest retrograde atrial activation outside the traditional location of the fast pathway (formerly described as “posterior” or “leftward inferior extension” or “left variant” slow-fast AVNRT) have been considered as a variant “slow-slow AVNRT.” In the latter setting, two slow pathways (the right and left inferior AVN extensions) are used in the AVNRT circuit. The very short (and occasionally nega-

tive) HA interval observed during tachycardia, despite retrograde conduction over a slow pathway, could be explained by the presence of a relatively long lower common pathway. Retrograde conduction over the slow pathway with simultaneous bystander conduction over the lower common pathway (from the distal junction of the two slow pathways to the HB) results in simultaneous atrial and ventricular activation and shortening of the recorded HA interval, which mimics slow-fast AVNRT.^{8,10} Older patients (>60 years) often have longer conduction times over the retrograde fast pathway, resulting in HA intervals similar to those in slow-slow AVNRT, but still with the earliest atrial activation at the tendon of Todaro.

Lower common pathway. The presence of a lower common pathway in typical AVNRT remains controversial. Nevertheless, it is recognized that the lower common pathway in typical AVNRT, if present, is very short (as assessed by the degree of HB prematurity required for a VES to reset the tachycardia, and by comparing the HA interval during AVNRT with that during ventricular pacing at the TCL).^{8,10,11}

AH/HA ratio. The AH interval is long (>200 milliseconds), due to anterograde conduction over the slow pathway. The HA interval is relatively short (<70 milliseconds) given the fast retrograde conduction. This produces an AH/HA ratio of greater than 1 and simultaneous atrial and ventricular activations (the onset of atrial activation appears before, at the onset, or just after the QRS complex).

Atypical (Fast-Slow) Atrioventricular Nodal Reentrant Tachycardia

Anterograde conduction. The nature of anterograde pathway conduction during fast-slow AVNRT remains poorly understood.⁷ Although this variant was initially thought of as using the same circuit as typical slow-fast AVNRT but in the reverse direction, recent data suggest that anterograde “fast pathway” during atypical AVNRT is distinct from the retrograde “fast pathway” during typical AVNRT. Some investigators have suggested that anterograde conduction during fast-slow AVNRT is mediated by a slow pathway, and that the fast pathway is a bystander that mediates conduction to the HB (and results in a short AH interval) but without contributing to the reentry circuit (analogous to AVNRT with ventricular preexcitation over a bystander bypass tract [BT]).^{7,8,10} Of note, patients with fast-slow AVNRT often exhibit multiple AH interval jumps during AES testing, which is consistent with the presence of multiple slow pathways, and supporting reentry between two “slow pathways.”

Retrograde conduction. A slow pathway forms the retrograde limb of the reentry circuit. The earliest retrograde atrial activation (over the slow pathway) during fast-slow AVNRT is traditionally reported at the base of the triangle of Koch, near the CS os (see Fig. 17.2). However, other locations are also frequent, including mid or superior septum, distal CS, or left side of the septum (see Fig. 17.2). Thus fast-slow

Fig. 17.2 Surface Electrocardiogram and Endocardial Recordings of the Different Types of Atrioventricular Nodal Reentrant Tachycardia (AVNRT). The dashed line marks the site with the earliest atrial activation. In slow-fast (typical) AVNRT, the initial site of atrial activation is usually recorded in the His bundle (HB) catheter. In slow-slow AVNRT, the P wave lies outside the QRS in the ST-T wave, and the RP interval is longer than that in slow-fast AVNRT. The earliest retrograde atrial activation is usually in the inferoposterior part of the triangle of Koch. Slow pathways with longer conduction times have a more inferior location in the triangle of Koch. In fast-slow AVNRT, the earliest site of retrograde atrial activation is usually recorded at the base of the triangle of Koch or coronary sinus ostium. An eccentric retrograde atrial activation sequence with the earliest retrograde activation site inside the CS can be observed in atypical fast-slow AVNRT. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; HRA, high right atrium; RVA, right ventricular apex.

AVNRT can be of posterior, anterior, or middle type according to the mapped location of the retrograde slow pathway.^{8,10}

Lower common pathway. A relatively long lower common pathway has been observed in fast-slow AVNRT, in contrast to slow-fast AVNRT.

AH/HA ratio. The AH interval is shorter than the HA interval (30 to 185 milliseconds vs. 135 to 435 milliseconds), resulting in long RP tachycardia and an AH/HA ratio less than 1.^{8,10} The long HA interval is a result of slow retrograde conduction over the slow pathway. The short AH interval represents anterograde conduction over the fast pathway; however, whether this pathway serves as the anterograde limb of the reentry circuit, or as just a bystander, is being debated.

Atypical (Slow-Slow) Atrioventricular Nodal Reentrant Tachycardia

As the name implies, the reentrant circuit in slow-slow AVNRT uses two slow pathways (the right and left inferior AVN extensions). These patients often exhibit multiple AH interval jumps during AES testing, which is consistent with multiple slow pathways.

Anterograde conduction. A slow pathway forms the anterograde limb of the reentry circuit. Data suggest the slow pathway used for anterograde conduction in slow-slow AVNRT is similar to the one used for retrograde conduction during fast-slow AVNRT.¹³

Retrograde conduction. A second slow (or “intermediate”) pathway serves as the retrograde limb of the reentry circuit. The earliest retrograde

Fig. 17.3 Retrograde Atrial Activation During Typical Atrioventricular Nodal Reentrant Tachycardia. Sinus rhythm is shown on the left, slow-fast atrioventricular nodal reentrant tachycardia is shown in the center, and ventricular pacing during sinus rhythm appears on the right. The dashed line denotes earliest atrial activation (proximal CS, near ostium), significantly before the His bundle atrial activation (most visible during ventricular pacing). *CS_{dist}*, Distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *His_{dist}*, distal His bundle; *His_{mid}*, middle His bundle; *His_{prox}*, proximal His bundle; *HRA*, high right atrium; *RV*, right ventricle; *SVT*, supra-ventricular tachycardia.

atrial activation occurs along the roof of the proximal CS (1 to 3 cm from the CS os) or, less commonly, at the inferoposterior aspect of the triangle of Koch (see Fig. 17.2). Of note, patients with this form of AVNRT can also have retrograde conduction over the fast pathway, which can be demonstrated during ventricular pacing, which is not part of the reentrant circuit.¹³

Lower common pathway. Slow-slow AVNRT exhibits a relatively long lower common pathway, significantly longer than that in typical AVNRT.

AH/HA ratio. The AH interval is long (>200 milliseconds) due to the slow retrograde conduction over the slow pathway. The HA interval is often shorter than the AH interval, but is usually greater than 70 milliseconds, and the AH/HA ratio remains greater than 1. The short HA interval observed during slow-slow AVNRT (despite retrograde conduction over a slow pathway) could be explained by the presence of a relatively long lower common pathway. Retrograde conduction over the slow pathway with simultaneous bystander conduction over the lower common pathway (from the distal junction of the two slow pathways to the HB) results in simultaneous atrial and ventricular activation, and shortening of the recorded HA interval, which mimics slow-fast AVNRT.

Although the HA interval during slow-slow AVNRT is usually longer than that during slow-fast AVNRT, a significant overlap exists. Slow-slow AVNRT can exhibit very short AH intervals, mimicking slow-fast AVNRT. In fact, this form of AVNRT was considered a variant of slow-

fast AVNRT, formerly described as “posterior” or “type B” AVNRT (which accounted for approximately 2% of patients with slow-fast AVNRT). Nonetheless, several features of slow-slow AVNRT can help distinguish it from slow-fast AVNRT, including: (1) the earliest retrograde atrial activation is recorded at the roof of the CS or at the inferior triangle of Koch, rather than the fast pathway area; (2) there is a much wider range of HA intervals; (3) there is a much more common cycle length (CL) changes and especially changes in HA interval during tachycardia; and (4) there is a relatively long lower common pathway (HA interval during ventricular pacing at the TCL exceeding the HA interval during tachycardia [Δ HA] by ≥ 15 milliseconds).

Epidemiology

AVNRT is the most common form of paroxysmal supraventricular tachycardia (SVT). The absolute number of patients with AVNRT and its proportion of paroxysmal SVT increase with age. The reason may be related to the normal evolution of AVN physiology over the first two decades of life, as well as to age-related changes in atrial and AVN physiology observed in later decades. AVNRT is unusual in children younger than 5 years, and it typically initially manifests in early adult life (e.g., in the teens). Conversely, atrioventricular reentrant tachycardia (AVRT) manifests earlier, with an average of more than 10 years separating the time of clinical presentation of AVRT and that of AVNRT. AVNRT onset has been reported after the age of 50 years in 16% and before the age of 20 years in 18%.¹⁴ There is also a striking 2:1

predominance of AVNRT in women, in whom symptoms start at a significantly younger age. As such, female sex and older age (i.e., teens vs. newborns or young children) favor the diagnosis of AVNRT over AVRT. Gender differences in the anterograde and retrograde AVN EP properties have been observed and may contribute to the pathogenesis of AVNRT.¹⁵ There is no significant association of AVNRT with other types of structural heart disease; patients with ventricular tachycardia (VT) in the absence of structural heart disease have a higher prevalence of AVNRT.

Clinical Presentation

Patients with AVNRT typically present with the clinical syndrome of paroxysmal SVT. This is characterized as regular rapid tachycardia of abrupt onset and termination. Patients commonly describe palpitations and dizziness. Rapid ventricular rates can be associated with complaints of dyspnea, weakness, chest pain, or presyncope, and can at times be disabling. True syncope is uncommon but can occur, especially in elderly patients. Episodes can last from seconds to several hours. AVNRT can occur spontaneously or on provocation with exertion, caffeine, or alcohol. Patients often learn to use certain maneuvers, such as the carotid sinus massage or the Valsalva maneuver, to terminate the arrhythmia, although many require pharmacological treatment.¹⁴

About half of patients with typical AVNRT report experiencing a pounding sensation in the neck during tachycardia, which likely is related to pulsatile reversed flow when the RA contracts against a closed tricuspid valve due to simultaneous contraction of atria and ventricles. The physical examination correlate of this phenomenon is continuous pulsing cannon A waves in the jugular venous waveform (described as the “frog” sign). This clinical feature has been reported to distinguish paroxysmal SVT resulting from AVNRT from that caused by orthodromic AVRT. Although atrial contraction during AVRT occurs against closed AV valves, the longer VA interval results in separate ventricular and then atrial contraction and a relatively lower RA and venous pressure. Therefore the presence of palpitations in the neck is experienced less commonly (about 17%) in patients with AVRT.¹⁵ Polyuria is particularly common with AVNRT and is related to higher right atrial pressures and elevated levels of atrial natriuretic protein in patients with AVNRT compared with patients who have AVRT or AFL.¹⁴

INITIAL EVALUATION

History, physical examination, and 12-lead ECG constitute an appropriate initial evaluation. In patients with brief, self-terminating episodes, an event recorder is the most effective way to obtain ECG documentation. An echocardiographic examination should be considered in patients with documented sustained SVT to exclude the possibility of structural heart disease. Further diagnostic studies (e.g., cardiac stress testing) are indicated only if there are signs or symptoms that suggest structural heart disease.

The diagnosis of AVNRT as the mechanism of SVT can be strongly suspected based on the surface ECG but can be difficult to confirm, especially when only single-lead rhythm strips are available during the SVT. However, EP testing is not indicated unless a decision to proceed with catheter ablation is undertaken.

PRINCIPLES OF MANAGEMENT

Acute Management

Because maintenance of AVNRT is dependent on AVN conduction, maneuvers or drugs that slow AVN conduction and prolong AVN refractoriness can be used to terminate the tachycardia. Initially, maneuvers that increase vagal tone (e.g., Valsalva maneuvers, gagging, carotid sinus

Fig. 17.4 Acute Treatment of Atrioventricular Nodal Reentrant Tachycardia (AVNRT). ^aFor rhythms that break or recur spontaneously, synchronized cardioversion is not appropriate. IV, Intravenous. (From Page RL, Joglar JA, Caldwell MA, et al. 2015 ACC/AHA/HRS guideline for the management of adult patients with supraventricular tachycardia: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines and the Heart Rhythm Society. *J Am Coll Cardiol*. 2016;67:e27–e115.)

massage) are used. When vagal maneuvers are unsuccessful, tachycardia termination can be achieved with antiarrhythmic drugs whose primary effects increase refractoriness or decrease conduction (negative dromotropic effect) over the AVN (Fig. 17.4). Adenosine is the drug of choice and is successful in more than 95% of cases. In addition, intravenous (IV) diltiazem and verapamil are particularly effective in terminating AVNRT and can be used in hemodynamically stable patients. Beta-blockers are also a reasonable option. Digoxin, which has a slower onset of action than the other AVN blockers, is not favored for the acute termination of AVNRT, except if there are relative contraindications to the other agents.¹⁴

Class IA and IC sodium channel blockers can also be used in treating an acute event of AVNRT when other regimens have failed, a strategy that is rarely needed. Electrical cardioversion is recommended for hemodynamically unstable patients and those with persistent arrhythmia refractory to pharmacological therapy. Energies in the range of 10 to 50 J are usually adequate.¹⁴

Chronic Management

Because AVNRT is generally a benign arrhythmia that does not influence survival, the primary indication for its treatment relates to its impact on a patient's quality of life (Fig. 17.5). Factors that contribute to the therapeutic decision include the frequency and duration of tachycardia, tolerance of symptoms, the effectiveness and tolerance of antiarrhythmic drugs, the need for lifelong drug therapy, and the presence

Fig. 17.5 Ongoing Management of Atrioventricular Nodal Reentrant Tachycardia (AVNRT). Drugs listed alphabetically. SHD, Structural heart disease (including ischemic heart disease). (From Page RL, Joglar JA, Caldwell MA, et al. 2015 ACC/AHA/HRS guideline for the management of adult patients with supraventricular tachycardia: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines and the Heart Rhythm Society. *Circulation*. 2016; 133:e506–e574.)

of concomitant structural heart disease. Patients who develop a highly symptomatic episode of paroxysmal SVT, particularly if it requires an emergency room visit for termination, may elect to initiate therapy after a single episode. In contrast, a patient who presents with minimally symptomatic episodes of paroxysmal SVT that terminate spontaneously or in response to Valsalva maneuvers may elect to be followed clinically without specific therapy. These patients should be taught how to correctly perform vagal maneuvers and be educated about when to seek medical attention.¹⁴

Catheter Ablation

Once it is decided to initiate treatment for AVNRT, the question arises whether to initiate pharmacological therapy or to use catheter ablation. Because of its high efficacy (>95%) and low incidence of complications, catheter ablation has become the preferred therapy over long-term pharmacological therapy and can be offered as an initial therapeutic option. It is reasonable to discuss catheter ablation with all patients suspected of having AVNRT. However, patients considering radiofrequency (RF) ablation must be willing to accept the risk, albeit low, of AV block and pacemaker implantation.^{14,16}

Pharmacological Therapy

For patients with AVNRT who are not candidates for, or prefer not to undergo, catheter ablation, long-term pharmacological therapy can be effective in 30% to 60% of patients. Most pharmacological agents that depress AVN conduction (including beta-blockers and calcium channel blockers) can reduce the frequency of recurrences of AVNRT. If those agents are ineffective, class IC (flecainide or propafenone in patients without structural or ischemic heart disease) or class III antiarrhythmic agents (sotalol or dofetilide) may be considered. Given the potential adverse effects of digoxin and amiodarone, these agents are generally reserved as last-resort therapy.^{14,16}

Outpatients may use a single dose of verapamil, diltiazem, or propranolol to acutely terminate an episode of AVNRT. This so-called pill-in-the-pocket approach (i.e., administration of a drug only during an episode of tachycardia for the purpose of termination of the arrhythmia when vagal maneuvers alone are not effective) is appropriate to consider for patients with infrequent episodes of AVNRT that are prolonged but well tolerated, and it obviates exposure of patients to long-term and unnecessary therapy between rare arrhythmic events. This approach necessitates the use of a drug that has a short onset of action

(i.e., immediate-release preparations). Candidate patients should be free of significant LV dysfunction, sinus bradycardia, and preexcitation. Single-dose oral therapy with diltiazem (120 mg) plus propranolol (80 mg) has been shown to be superior to both placebo and flecainide in terminating AVNRT.¹⁴

ELECTROCARDIOGRAPHIC FEATURES

Electrocardiographic Manifestations of Dual Atrioventricular Nodal Physiology

As noted, dual pathway physiology characterizes the normal AVN electrophysiology, which is prevalent in most normal individuals. However, the ECG normally reveals only the conduction of the fast pathway, while slow pathway conduction generally remains concealed. The most common ECG manifestation of dual AVN physiology is AVNRT. In addition, several ECG manifestations can be explained by dual pathways physiology.^{3,2,6}

Two Families of PR Intervals

A shift of anterograde conduction from the fast pathway to the slow pathway can manifest as sudden prolongation of the PR interval, and vice versa (Fig. 17.6). This shift can occur spontaneously and result in alternans of the PR interval (i.e., long and short PR intervals alternate with each other) or manifest as two families of PR intervals (short and long), with sudden and sustained prolongation or shortening of the PR interval that can be observed on different occasions. The shift also can be precipitated by a change in autonomic tone or by a PAC or a PVC that causes conduction block or concealment in one pathway and allows conduction over the other (Fig. 17.7).^{6,17}

Dual Ventricular Response to a Single Supraventricular Beat

Rarely, a single atrial impulse (e.g., PAC) can conduct simultaneously along the slow and fast pathways, producing two QRS complexes (“double fire”). The reverse can also occur, with two atrial impulses from one ventricular complex.

Rapid Ventricular Rates During Atrial Fibrillation

Ventricular rates during AF can exhibit a bimodal distribution of R-R intervals on Holter recordings. The shorter R-R intervals (the faster ventricular rates) are believed to be a result of conduction over the slow pathway (because of its shorter refractory periods), while the fast pathway mediates relatively slower ventricular rates. Ablation of the slow AVN pathways in these patients can potentially eliminate the fast ventricular rates and produce a unimodal R-R interval distribution.⁶

Electrocardiographic Manifestations of Atrioventricular Nodal Reentrant Tachycardia

P Wave Morphology

In typical (slow-fast) AVNRT, the P wave is usually not visible because of the simultaneous atrial and ventricular activation. The P wave can distort the initial portion of the QRS (mimicking a q wave in the inferior leads), lie just within the QRS (inapparent), or distort the terminal portion of the QRS (mimicking an s wave in the inferior leads or a terminal r wave in lead V1) (Fig. 17.8). When apparent, the P wave is significantly narrower than the sinus P wave, and is negative in the inferior leads, findings that are consistent with concentric retrograde atrial activation over the fast AVN pathway. In atypical AVNRT, the P wave is relatively narrow, negative in the inferior leads, and positive in lead V1 (see Fig. 17.8).⁸ Compared to orthodromic AVRT using a

Fig. 17.6 Dual Atrioventricular Node Physiology Manifesting as Two Different PR Intervals During Normal Sinus Rhythm. Note that the shift in atrioventricular conduction from the fast to the slow atrioventricular node pathway (arrow) occurs without any changes in the sinus cycle length (680 milliseconds). This phenomenon indicates that the fast pathway anterograde effective refractory period is long relative to the sinus cycle length. AH, Atrial-His bundle.

Fig. 17.7 Dual Atrioventricular Node Physiology. Sinus rhythm with atrioventricular conduction over the slow pathway and long PR and AH intervals (*to the left*). After a premature ventricular complex (PVC) that results in concealed retrograde conduction into the slow pathway, anterograde atrioventricular conduction shifts from the slow pathway to the fast pathway with sudden shortening of the PR interval. AH, Atrial-His bundle; CS_{dist}, distal coronary sinus; CS_{prox}, proximal coronary sinus; HRA, high right atrium; RVA, right ventricular apex.

posteroseptal BT; the retrograde P waves in slow-slow AVNRT are more negative in lead aVF (>0.16 mV negative amplitude).¹⁸

QRS Morphology

The QRS morphology during AVNRT is usually the same as in normal sinus rhythm (NSR). The development of prolonged functional aberration during AVNRT is uncommon, and it usually occurs following the induction of AVNRT by ventricular stimulation more frequently than by atrial stimulation, or following the resumption of 1:1 conduction to the ventricles after a period of block below the tachycardia circuit. At times, alternans of QRS amplitude can occur when the tachycardia rates are rapid. Occasionally, AVNRT can coexist with ventricular preexcitation over an AV BT, whereby the BT is an innocent bystander.

P-QRS Relationship

In typical (slow-fast) AVNRT, the RP interval is very short (−40 to 75 milliseconds). Variation of the P-QRS relationship with or without block can occur during AVNRT, especially in atypical variants of the tachycardia. This phenomenon usually occurs when the conduction system and the reentry circuit are unstable during initiation or termination of the tachycardia, which is likely secondary to decremental conduction in the lower common pathway. The ECG manifestation of P-QRS variations with or without AV block during tachycardia, especially at the initiation of tachycardias or in cases of nonsustained tachycardias, can be misdiagnosed as atrial tachycardias (ATs). Moreover, the variations can be of such magnitude that long RP tachycardia can masquerade for brief periods of time as short RP tachycardia.

Usually, the A/V ratio during AVNRT is equal to 1; however, 2:1 AV block can be present because of a block below the reentry circuit (usually below the HB and, infrequently, in the lower common pathway). In such cases, narrow, inverted P wave morphology in the inferior leads inscribed exactly between QRS complexes strongly suggests AVNRT (Fig. 17.9). The incidence of reproducible sustained 2:1 AV block during

induced episodes of AVNRT is approximately 10%. Rarely, VA block can occur because of a block in an upper common pathway; however, some of these cases may represent reentry using a retrogradely conducting nodofascicular or nodoventricular pathway with intranodal block above the level of the circuit (see Chapter 19).

In atypical (fast-slow) AVNRT, the RP interval is longer than the PR interval. In slow-slow AVNRT, the RP interval is usually shorter than, and sometimes equal to, the PR interval. Occasionally, the P wave is inscribed in the middle of the cardiac cycle, thus mimicking AT with 2:1 AV conduction (see Fig. 17.2). Slow-slow AVNRT can be associated with RP intervals and P wave morphology similar to that during orthodromic AVRT using a posteroseptal AV BT. However, although both SVTs have the earliest atrial activation in the posteroseptal region, conduction time from that site to the HB region is significantly longer in AVNRT than in orthodromic AVRT. The results are a significantly longer RP interval in lead V1 and a significantly larger difference in the RP interval between lead V1 and inferior leads during AVNRT. Therefore Δ RP interval (V1 − III) of more than 20 milliseconds suggests slow-slow AVNRT (sensitivity, 71%; specificity, 87%).⁸

ELECTROPHYSIOLOGICAL TESTING

EP testing is used to study the inducibility and mechanism of the SVT and to guide catheter ablation. Typically, three quadripolar catheters are positioned in the high RA, the right ventricular (RV) apex, and the HB region, and a decapolar catheter is positioned in the CS (see Fig. 4.4). A typical programmed electrical stimulation protocol used for EP testing in patients with AVNRT is outlined in Box 17.1.

Baseline Observations During Sinus Rhythm

Programmed Atrial Stimulation During Sinus Rhythm

Anterograde dual AVN physiology. Demonstration of anterograde dual AVN pathway conduction curves requires a longer ERP of the fast

Fig. 17.8 Electrocardiogram Morphology of the Different Types of Atrioventricular Nodal Reentrant Tachycardia (AVNRT). Arrows mark the P waves. In slow-fast (typical) AVNRT, the P wave may lie within the QRS (invisible, *first panel*) or distort the terminal portion of the QRS (mimicking an r wave in lead V1, *second panel*). In slow-slow AVNRT, the P wave lies outside the QRS in the ST-T wave, and the RP interval is longer than that in slow-fast AVNRT. In fast-slow AVNRT, the P wave lies before the QRS with a long RP interval. In all varieties of AVNRT, the P wave is relatively narrow, negative in the inferior leads, and positive in lead V1.

Fig. 17.9 Typical Atrioventricular Nodal Reentrant Tachycardia With Intermittent 2:1 Atrioventricular (AV) Block. His potential (*H*) is observed following conducted atrial impulses, but not after blocked atrial impulses, thus indicating AV block in the lower common pathway or in the portion of the His bundle proximal to the recording site. Note that intermittent AV block results in long-short cycle sequences associated with a right bundle branch block (RBBB) pattern during complexes conducted following a short cycle. RBBB is also observed intermittently during supraventricular tachycardia with 1:1 AV conduction. Note the lack of effect of RBBB on the tachycardia cycle length (A-A interval) or ventricular-atrial interval. *CS_{dist}*, Distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *HRA*, high right atrium; *RVA*, right ventricular apex.

BOX 17.1 Programmed Stimulation Protocol for Electrophysiological Testing of Atrioventricular Nodal Reentrant Tachycardia

Atrial burst pacing from the RA and CS (down to AV Wenckebach CL)
 Single and double AESs at multiple CLs (600–400 ms) from the high RA and CS (down to atrial ERP)
 Ventricular burst pacing from the RV apex (down to VA Wenckebach CL)
 Single and double VESs at multiple CLs (600–400 ms) from the RV apex (down to ventricular ERP)
 Administration of isoproterenol infusion as needed to facilitate tachycardia induction (0.5–4 µg/min)

AES, Atrial extrastimulus; AV, atrioventricular; CL, cycle length; CS, coronary sinus; ERP, effective refractory period; RA, right atrium; RV, right ventricle; VA, ventriculoatrial; VES, ventricular extrastimulus.

BOX 17.2 Dual Atrioventricular Node Physiology

Manifestations of Anterograde Dual Atrioventricular Node Physiology

- A “jump” in the AH interval of ≥ 50 ms in response to a 10-ms decrement of the AES coupling interval or atrial PCL
- Dual ventricular response to a single atrial beat (“double fire”)
- PR interval exceeding the R-R interval during rapid atrial pacing
- Two distinct PR or AH intervals during NSR or fixed-rate atrial pacing

Manifestations of Retrograde Dual Atrioventricular Node Physiology

- A “jump” in HA interval of ≥ 50 ms in response to a 10-ms decrement of the VES coupling interval or ventricular PCL
- Two atrial responses to a single ventricular impulse

AES, Atrial extrastimulation; AH, atrial-His; CL, cycle length; NSR, normal sinus rhythm; PCL, pacing cycle length; VES, ventricular extrastimulation.

pathway than the slow pathway ERP and the atrial functional refractory period (FRP), as well as a sufficient difference in conduction times between the two pathways. Dual AVN physiology can be diagnosed by demonstrating one of the following: (1) a “jump” in the AH interval in response to progressively more premature AES; (2) two ventricular responses to a single atrial impulse; (3) a PR interval exceeding the R-R interval during rapid atrial pacing; or (4) different PR or AH intervals during NSR or fixed-rate atrial pacing (Box 17.2).⁶

AH interval jump. In contrast to the normal pattern of AVN conduction, in which the AH interval gradually lengthens in response to progressively shorter AES (i.e., shorter coupling intervals), patients with dual AVN physiology usually demonstrate a sudden increase (“jump”) in the AH interval at a critical AES (A1-A2) coupling interval (eFig. 17.1). Conduction with a short PR or AH interval reflects fast pathway conduction, whereas conduction with a long PR or AH interval reflects slow pathway conduction. The AH interval jump signals block of anterograde conduction of the progressively premature AES over the fast pathway (once the AES coupling interval becomes shorter than the fast pathway ERP) and anterograde conduction over the slow pathway (which has an ERP shorter than the AES coupling interval), with a longer conduction time (i.e., longer A2-H2 interval). A jump in the A2-H2 (or H1-H2) interval of ≥ 50 milliseconds in response to a 10

millisecond shortening of either the A1-A2 interval (i.e., AES coupling interval) or the A1-A1 interval (i.e., pacing cycle length [PCL]) is defined as a discontinuous AVN function curve and is considered evidence of dual anterograde AVN pathways (see Fig. 4.23).

Two ventricular responses to a single atrial impulse. Rapid atrial pacing or AES can result in two ventricular complexes to a single paced atrial impulse (referred to as “1:2 response”).¹⁹ The first ventricular complex is caused by conduction of the atrial impulse over the fast AVN pathway, and the second complex is caused by conduction over the slow AVN pathway (Fig. 17.10). This response requires a unidirectional retrograde block in the slow AVN pathway. Typically, in the presence of dual AVN pathways, conduction propagates simultaneously over both fast and slow AVN pathways. However, the wavefront conducting down the fast pathway reaches the distal junction of the two pathways before the impulse conducting down the slow pathway; hence, it conducts retrogradely up the slow pathway to collide with the impulse conducting anterogradely down that pathway. Thus the anterograde impulse conducting down the slow pathway does not have the opportunity to reach the HB and the ventricle. Rarely, however, the slow pathway conducts only anterogradely or has a very long retrograde ERP. In this setting, the wavefront traveling anterogradely down the fast pathway blocks (but does not conceal) in the slow pathway retrogradely and fails to retard the impulse traveling anterogradely down that pathway. Consequently, the wavefront traveling down the slow pathway can reach the HB and ventricle to produce a second His potential and QRS in response to a single atrial impulse. Because retrograde block in the slow pathway is a prerequisite to a 1:2 response, when such a phenomenon is present, it indicates that the slow pathway cannot support reentrant tachycardia using the slow pathway as the retrograde limb. The 1:2 response should be differentiated from pseudo-simultaneous fast and slow pathway conduction, which is a much more common phenomenon during rapid atrial pacing. In the latter case, all paced atrial impulses block anterogradely in the fast pathway and conduct exclusively down the slow pathway with prolonged AH intervals (with PR intervals longer than atrial PCL), so that the last paced atrial impulse falls before the His potential caused by conduction of the preceding paced atrial impulse. Thus the last paced atrial impulse is followed by two His potentials and two ventricular complexes. The last response may then be followed by induction of AVN echo beats or AVNRT, mimicking simultaneous fast and slow pathway conduction (Fig. 17.11).

PR interval longer than RR interval. The PR interval gradually prolongs as the atrial pacing rate increases. When a critical pacing rate is reached, the PR interval typically exceeds the R-R interval, with all AVN conduction over the slow AVN pathway (see Fig. 17.11). This manifests as *crossing over* of the pacing stimulus artifacts and QRSs; that is, the paced atrial complex is conducting not to the QRS immediately following it, but rather to the next QRS, because of a very long PR interval. There should be consistent 1:1 AV conduction that remains stable over the span of several cycles for this observation to be interpreted (i.e., without Wenckebach block). Such slow AVN conduction, sometimes called “skipped P waves,” is seen only when conduction propagates over a slow AVN pathway, and it is not seen in the absence of dual AVN physiology. This phenomenon is diagnostic of the presence of dual AVN physiology, even in the absence of an AH interval jump and therefore is very helpful in patients with smooth AVN function curves. In fact, 96% of patients with AVNRT and smooth AVN function curves have a PR/RR interval ratio greater than 1 (i.e., PR interval longer than PCL) during atrial pacing at the maximal rate with consistent 1:1 AV conduction (vs. 11% in controls).

Two distinct AH intervals during NSR or at identical atrial PCLs. This phenomenon can occur when the fast pathway anterograde ERP is long relative to the sinus or paced CL (see Fig. 17.6). Such a

eFig. 17.1 Dual Atrioventricular Node Physiology. H_1-H_2 intervals (*left*) and A_2-H_2 intervals (*right*) are at various A_1-A_2 intervals, with a discontinuous atrioventricular nodal curve. At a critical A_1-A_2 interval, the H_1-H_2 and A_1-H_2 intervals increase markedly. At the break in the curves, atrioventricular nodal reentrant tachycardia is initiated. (From Olgin JE, Zipes DP. Specific arrhythmias: diagnosis and treatment. In: Libby P, Bonow RO, Mann DL, Zipes DP, eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 7th ed. Philadelphia: Saunders; 2008:880.)

Fig. 17.10 Dual Atrioventricular Node (AVN) Physiology: Two Ventricular Complexes to a Single Paced Atrial Impulse. Rapid atrial pacing during normal sinus rhythm. Each paced atrial impulse conducts anterogradely over the fast AVN pathway (red arrows). However, the last paced impulse conducts anterogradely over both the fast (red arrow) and slow (blue arrow) pathways, resulting in two His bundle and ventricular responses. *CS_{dist}*, Distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *HRA*, high right atrium; *RVA*, right ventricular apex.

phenomenon also requires a long retrograde ERP of the fast pathway. Otherwise, AVN echo beats or AVNRT would result, because once the impulse blocks anterogradely in the fast pathway and is conducted down the slow pathway, it would subsequently conduct retrogradely up the fast pathway if the ERP of the fast pathway were shorter than the conduction time (i.e., shorter than the AH interval) over the slow pathway.

Determinants for the occurrence of sustained slow pathway conduction include markedly abnormal, anterograde and retrograde conduction properties of the fast pathway and, possibly, differential sensitivity to vagal activity of the fast pathway, compared with the slow pathway.¹⁷

Multiple AVN pathways. Multiple AH interval “jumps” in response to AES, a finding suggesting the presence of multiple AVN pathways, can be observed in up to 14% of patients with AVNRT, especially in those with atypical variants of AVNRT. These phenomena are characterized by multiple AH interval jumps of 50 milliseconds or more in response to an increasingly premature AES. In these patients, a single AES can initiate multiple jumps in only 68%, whereas double AESs or atrial pacing is required in 32%. Such patients can have AVNRT with longer TCLs and longer ERP and FRP of the AVN. It is uncommon for multiple AVNRTs with different TCLs and P-QRS relationships to be present in the same patient.

Prevalence of dual AVN physiology. The presence of dual AVN pathways can usually be demonstrated by using a single AES or atrial pacing in 85% of patients with clinical AVNRT. In 95% of patients, the presence of dual AVN pathways can be revealed by using multiple AESs, multiple-drive CLs (typically 600 and 400 milliseconds), and multiple pacing sites (typically high RA and CS).

Occasionally, the AH interval continuously prolongs (without a discrete “jump”) in response to more premature AES, with “smooth transition” of anterograde conduction from the fast pathway to the slow pathway, until retrograde conduction starts over the “fast pathway”

and AVNRT is induced. Failure to demonstrate dual AVN physiology in patients with AVNRT can be caused by minimal differences in the anterograde refractory periods of the fast and slow AVN pathways. In this setting, dissociation of refractoriness of the fast and slow AVN pathways is required and can be achieved by any of the following: (1) introduction of an AES at a shorter pacing drive CL; (2) introduction of multiple AESs; (3) burst atrial pacing; or (4) pharmacological modulation of AVN dual pathway conduction and refractoriness.⁶

In general, if fast pathway conduction is suppressed at baseline (as evidenced by a long AH interval at all atrial pacing rates or VA block during ventricular pacing), isoproterenol infusion (and occasionally atropine) usually facilitates fast pathway conduction. In contrast, if the baseline ERP of the fast pathway is very short, conduction over the slow pathway can be difficult to document. Increasing the degree of sedation or infusion of esmolol can prolong the fast pathway ERP and allow recognition of slow pathway conduction.

Another potential reason for the inability to demonstrate dual AVN physiology is a block in the fast AVN pathway at the pacing drive CL (i.e., fast pathway ERP is longer than pacing drive CL). In addition, atrial FRP can limit the prematurity of the AES. Consequently, AVN activation cannot be adequately advanced to produce block in the fast pathway because a more premature AES would result in more intraatrial conduction delay and less premature stimulation of the AVN. This obstacle can be overcome by the introduction of an AES following a shorter pacing drive CL, introduction of multiple AESs, burst atrial pacing, or stimulation from multiple atrial sites.

Programmed Ventricular Stimulation During Sinus Rhythm

Retrograde dual AVN physiology. Demonstration of retrograde dual AVN pathway conduction curves requires a longer retrograde ERP of the fast pathway than slow pathway ERP and ventricular and His-Purkinje system (HPS) FRP, as well as a sufficient difference in

Fig. 17.11 Induction of Typical Atrioventricular Nodal Reentrant Tachycardia (AVNRT) With Atrial Pacing.

(A) Each of the atrial paced impulses (*S1*) conducts anterogradely over the slow atrioventricular node (AVN) pathway. The last paced impulse, following anterograde conduction down the slow pathway, also conducts retrogradely up the fast AVN pathway to initiate typical AVNRT with right bundle branch block (RBBB). (B) Each of the atrial paced impulses conducts anterogradely over the slow AVN pathway with a long PR interval (*blue arrows*); this is longer than the pacing cycle length, resulting in crossing over, which can mimic a 1:2 atrioventricular response caused by anterograde conduction over both the fast and slow AVN pathways. Following anterograde conduction down the slow pathway, the last paced impulse also conducts retrogradely over the fast pathway, initiating typical AVNRT. Red arrows illustrate atrial activation sequence during atrial pacing versus AVNRT. (C) Atrial pacing from the coronary sinus ostium induces typical AVNRT. Each of the atrial paced impulses (*S1*) conducts over the fast AVN pathway except for the last paced impulse, which conducts over both the fast and slow AVN pathways (*blue arrows*), resulting in a 1:2 response (i.e., 2 ventricular responses to a single atrial impulse); this is followed by induction of typical AVNRT with RBBB. The possibility of conduction of the paced atrial beats over the slow AVN pathway with a long atrial–His bundle (AH) interval (longer than the paced cycle length) is unlikely because the His potential preceding the first tachycardia complex (indicated by the *green arrow*) occurs later (i.e., at a longer AH interval) than what would be expected if that His potential was actually a result of conduction of the last atrial stimulus (as compared with the previous AH intervals). *CS_{dist}*, Distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *HRA*, high right atrium; *RVA*, right ventricular apex.

conduction times between the two pathways. In a pattern analogous to that of anterograde dual AVN physiology, ventricular stimulation can result in discontinuous retrograde AVN function curves, manifesting as a jump in the H2-A2 (or A1-A2) interval of 50 milliseconds or more in response to a 10 millisecond decrement of the VES coupling interval (V1-V2) or ventricular PCL (V1-V1). This finding must be distinguished from sudden VA prolongation caused by VH interval (but not HA interval) prolongation related to retrograde functional block in the right bundle branch (RB) and transseptal activation of HB through the left bundle branch (LB) (see eFig. 4.9). A 1:2 response (i.e., two atrial responses to a single ventricular stimulus) can also be observed (see Box 17.2).

Failure to demonstrate retrograde dual AVN physiology in patients with atypical AVNRT can be caused by similar fast and slow AVN pathway retrograde refractory periods. Dissociation of refractoriness of the fast and slow AVN pathways may be required and usually can be achieved by any of the following: (1) introduction of VESs at a shorter pacing drive CL; (2) introduction of multiple VESs; (3) burst ventricular pacing; or (4) administration of drugs such as beta-blockers, verapamil, or digoxin. In addition, retrograde block in the fast AVN pathway at the pacing drive CL (i.e., the PCL is shorter than the fast pathway ERP) and ventricular or HPS FRP interval limiting the prematurity of the VES can also account for such failure.

Differential-site RV pacing. Differential-site RV pacing can help exclude the presence of a retrogradely conducting septal AV BT. The response to differential RV pacing can be evaluated by comparing two variables between RV basal and RV apical (or midseptal) pacing: the VA interval (i.e., the stimulus-to-atrial [SA] interval) and atrial activation sequence (see Fig. 18.28). This maneuver is discussed in detail in Chapter 20.²⁰

The RV apical septum, although anatomically more distant from the atrium than the RV base, is nonetheless electrically closer because of the proximity of the distal RB to the pacing site. As a result, in the absence of a retrogradely conducting septal AV BT, pacing at the RV apex allows entry into the rapidly conducting HPS and results in a shorter VA interval during pacing from the apex than from the base. In addition, retrograde atrial activation sequence remains constant during pacing both at the RV apex and at the RV base because the atrium is activated over a single route (the AVN) in both settings.

A shorter VA interval during RV basal pacing than during RV apical pacing or a change in retrograde atrial activation sequence in response to differential RV pacing (RV base vs. RV apex) indicates the presence of an AV BT. However, differential-site RV pacing does not exclude the presence of a distant right or left free-wall BT or slowly conducting BT, whereby retrograde conduction occurs preferentially over the AVN.²⁰ Also, the occurrence of right bundle branch block (RBBB) (but not left bundle branch block [LBBB]) also can alter the significance of the VA interval criterion (see Fig. 20.6).

Para-Hisian Pacing During Sinus Rhythm

Para-Hisian pacing helps exclude the presence of a septal AV BT, which can mediate orthodromic AVRT with a retrograde atrial activation sequence similar to that during AVNRT. In the absence of a BT, para-Hisian pacing results in a shorter SA (or VA) interval when the HB-RB is captured ($S - H = 0$ and $SA = HA$) than the SA interval when only the ventricle is captured ($SA = S - H + HA$) with no change in the atrial activation sequence or HA interval. This response to para-Hisian pacing is termed *pattern 1* or *AVN/AVN pattern*.

A change in the retrograde atrial activation sequence with loss of HB-RB capture indicates the presence of a retrogradely conducting BT. Similarly, an SA (VA) interval that is constant regardless of whether the HB RB is being captured indicates the presence of a BT, whereas

prolongation of the SA (or VA) interval on loss of HB capture, compared with that during HB capture, excludes the presence of a retrogradely conducting BT, except for slowly conducting and far free-wall BTs. Please refer to Chapter 20 for a more detailed discussion of para-Hisian pacing.

Induction of Tachycardia

Initiation by Programmed Atrial Stimulation

Typical (slow-fast) AVNRT. Clinical AVNRT almost always can be initiated with an AES that blocks anterogradely in the fast pathway, conducts down the slow pathway, and then conducts retrogradely up the fast pathway. Only when anterograde conduction down the slow pathway is slow enough ("critical AH interval") to allow for recovery of the fast pathway to conduct retrogradely does reentry occur (see eFig. 17.1). This critical AH interval is not a fixed interval. It can change with changes in pacing drive CL, changes in autonomic tone, or after drug administration, thus reflecting changes in the fast pathway retrograde ERP.

There is a zone of AES coupling intervals (A1-A2) associated with AVNRT induction called the tachycardia zone. This zone usually begins at coupling intervals associated with marked prolongation of the AH intervals. This AVN conduction delay (AH interval prolongation), and not the AES coupling interval, is of prime importance for the genesis of AVNRT.

Atrial pacing can initiate AVNRT at PCLs associated with sufficient AVN conduction delay (see Fig. 17.11), especially during atypical Wenckebach periodicity, when anterograde block occurs in the fast pathway and conduction shifts to the slow pathway.

Rarely, AES or atrial pacing can produce a "1:2 response" with anterograde conduction over both the fast and slow pathways, as explained earlier (see Fig. 17.11). Such a response predicts easy induction of slow-fast AVNRT by ventricular stimulation because poor slow pathway retrograde conduction would increase the opportunity for the ventricular stimulus to block in the slow pathway and conduct up the fast pathway to return down the slow pathway and initiate AVNRT.

The site of atrial stimulation can affect the ease of inducibility of AVNRT, probably because of different atrial inputs to the AVN or different atrial FRPs. Therefore it is important to perform atrial stimulation from both the RA and CS.

AVN echo beats and AVNRT usually occur at the same time that dual pathways are revealed (see Fig. 4.23). In 20% of patients, the dual AVN pathway AH interval jump occurs without concurrent occurrence of echo beats or AVNRT because of failure of retrograde conduction up the fast pathway. This failure can be caused by the absence of a distal connection between the two AVN pathways, a long retrograde ERP of the fast AVN pathway, or concealment of the AES anterogradely into the fast AVN pathway (i.e., the AES propagates some distance into the fast pathway before being blocked). The last event results in anterograde postdepolarization refractoriness, which would consequently make the fast pathway refractory to the wavefront invading it in the retrograde direction. The latter phenomenon can be diagnosed by demonstrating that the AH interval following the AES that fails to produce an echo beat is longer than the shortest ventricular PCL with 1:1 retrograde conduction. Such a PCL is a marker of the fast pathway retrograde ERP. This finding implies that an AES blocking in the fast pathway and conducting over the slow pathway, with an AH interval exceeding fast pathway ERP and still not conducting retrogradely over the fast pathway, is caused by anterograde concealment (and not just block) into the fast pathway.

Markers of poor retrograde conduction over the fast AVN pathway predict difficulty inducing AVNRT. These markers include the absence of VA conduction, poor VA conduction (manifest as retrograde AVN

Wenckebach CL longer than 500 milliseconds), and retrograde dual pathways (indicative of long retrograde ERP of the fast pathway, which must exceed the refractoriness of the slow pathway for retrograde dual pathways to be demonstrable). In fact, retrograde fast AVN pathway characteristics (i.e., ERP) are the major determinant of *whether* reentry (AVN echoes or AVNRT) occurs, whereas conduction delay anterogradely over the slow pathway (i.e., “critical AH interval”) determines *when* reentry is to occur.

Although isolated AVN echoes can occur as long as VA conduction is present, the ability to initiate sustained AVNRT also requires the capability of the slow pathway to sustain repetitive anterograde conduction. In other words, sustenance of AVNRT requires that the TCL be longer than the ERP of all components of the circuit. Typically, for AVN reentry to occur, the fast pathway should be able to support 1:1 VA conduction at a ventricular PCL shorter than 400 milliseconds (i.e., retrograde Wenckebach CL shorter than 400 milliseconds), and the slow pathway should be able to support 1:1 AV conduction at an atrial PCL shorter than 350 milliseconds (i.e., anterograde Wenckebach CL shorter than 350 milliseconds). The shorter the AH interval during anterograde conduction over the fast pathway, the better the retrograde conduction over the same pathway (i.e., the shorter the HA interval), and the better the inducibility of AVNRT. Nevertheless, it is important to recognize that during EP testing, these criteria are dependent on the cardiac autonomic tone at that moment, and they can change dramatically by changing the level of patient sedation or the use of isoproterenol

or by prolonged periods of rapid pacing (particularly ventricular) that cause hypotension and a reflex increase in adrenergic tone, which then affect inducibility of AVNRT.

Atypical AVNRT. Anterograde dual AVN physiology is usually not demonstrable in patients with atypical AVNRT. In addition, as noted, the presence of a “1:2 response” to AES predicts noninducibility of atypical AVNRT because it indicates failure of the slow pathway to support retrograde conduction, a prerequisite for the atypical AVNRT circuit.

When atypical AVNRT is initiated with atrial stimulation, it is usually with modest prolongation of the AH interval over the fast pathway and anterograde block in the slow pathway, followed by retrograde slow conduction over the slow pathway (Fig. 17.12). Therefore a critical AH interval delay is not obvious.

Initiation by Programmed Ventricular Stimulation

Typical (slow-fast) AVNRT. Ventricular stimulation induces typical AVNRT by different mechanisms. The most common mechanism involves retrograde block of the ventricular stimulus in the slow pathway and retrograde conduction up the fast pathway, followed by anterograde conduction down the slow pathway. This occurs when the retrograde ERP of the slow pathway exceeds that of the fast pathway. This means that induction occurs without the demonstration of retrograde dual AVN physiology, and no critical VA or HA interval is required for induction. Occasionally, an interpolated

Fig. 17.12 Induction of Fast-Slow Atrioventricular Nodal Reentrant Tachycardia (AVNRT) With Atrial Extrastimulation (AES). AES delivered from the high right atrium (HRA) at a coupling interval of 270 milliseconds after a drive cycle length (CL) of 500 milliseconds initiated atypical AVNRT with a CL of 490 milliseconds. Note that the AES conducted with only a modest prolongation of the atrial–His bundle (AH) interval. In addition, comparing the AH interval between atrial drive pacing and that during the SVT (because the tachycardia CL approximates the pacing CL) reveals that ΔAH ($AH_{\text{pacing}} - AH_{\text{SVT}}$) is more than 40 milliseconds, thus favoring AVNRT over atrial tachycardia and orthodromic atrioventricular reentrant tachycardia. CS_{dist} , Distal coronary sinus; CS_{prox} , proximal coronary sinus; HRA, high right atrium; RVA, right ventricular apex.

PVC can block in the slow pathway retrogradely and penetrate the fast pathway and cause concealment, so that the fast pathway will be refractory when the next sinus beat occurs. The sinus beat would then block in the fast pathway and conduct down the slow pathway and initiate typical AVNRT. This mechanism is uncommon. Retrograde VA conduction over the fast AVN pathway is usually good, and VA block rarely occurs in patients with typical AVNRT initiated by ventricular stimulation.

Ventricular stimulation is less effective than atrial stimulation in inducing typical AVNRT (success rate is approximately 10% with VES and 40% with ventricular pacing), whereas atypical AVNRT can be induced almost as frequently by ventricular stimulation as by atrial stimulation. It is difficult for VES to induce typical AVNRT because the prematurity with which the VES arrives at the AVN can be limited by conduction delay in the HPS or in the lower common pathway. The ERP of the HPS may exceed that of the slow AVN pathway. This limitation can usually be overcome by the introduction of multiple VESs, use of a shorter drive CL, or ventricular pacing, which results in the adaptation and shortening of the HPS ERP. In addition, the anterograde ERP of the slow pathway may exceed the ventricular PCL so that the slow pathway is incapable of anterograde conduction of the ventricular impulse conducting retrogradely over the fast pathway. Similar retrograde ERPs of the slow and fast pathways also can limit the successful initiation of AVNRT by ventricular stimulation. As noted, manipulation of the autonomic tone with vagal maneuvers or drugs can facilitate dissociation of those ERPs. Another explanation for the lower success rate of AVNRT induction by ventricular stimulation is that the ventricular stimulus can penetrate (and not just block) in the slow pathway retrogradely, thus causing concealment that renders that pathway refractory and incapable of anterograde conduction of the ventricular impulse traveling retrogradely over the fast pathway.

Burst ventricular pacing can overcome many of the problems imposed by HPS refractoriness in the induction of typical AVNRT (Fig. 17.13). During ventricular pacing, the AVN is the primary site of conduction delay. However, block in the lower common pathway and repetitive

concealment (not just block) in the slow AVN pathway can still limit the success of ventricular pacing in inducing typical AVNRT.

When induction of the SVT is achieved by ventricular pacing at a CL similar to the subsequent TCL or by a VES that activates the HB at a coupling interval (i.e., H1-H2 interval) similar to the H-H interval during the SVT (i.e., similar to the TCL), the HA interval following the initiating ventricular stimulus then is compared with that during the SVT. During AVNRT, the HA interval of the ventricular stimulus initiating the SVT is longer than the HA interval during the SVT because both the HB and atrium are activated in sequence during ventricular stimulation but in parallel during AVNRT (Fig. 17.14). This is even exaggerated by the fact that the AVN usually exhibits greater decremental conduction with repetitive engagement of impulses than in response to a single impulse at a similar coupling interval. Therefore the more prolonged the HA interval with the initiating ventricular stimulus, the more likely the SVT is AVNRT. On the other hand, if the SVT uses an AV BT for retrograde conduction, the HA interval during the initiating ventricular stimulus (at a coupling interval comparable to the TCL) is shorter than that during orthodromic AVRT because the HB and atrium are activated in parallel during ventricular pacing (when atrial activation is mediated by retrograde BT conduction), but in sequence during SVT.

The intervals immediately following tachycardia initiation with a VES (delivered from the RV apex) provide data that are essentially equivalent to those observed with ventricular entrainment (see below). The interval from the VES to atrial activation (surface VA or "SA" interval) is compared to the surface VA interval during SVT, and the post VES return cycle (i.e., the interval from the VES to the subsequent RV apical depolarization) is compared to the TCL. An SA interval that exceeds the surface VA interval during SVT by less than 85 milliseconds is consistent with orthodromic AVRT. Similarly, a post VES return cycle exceeding the TCL by less than 115 milliseconds indicates orthodromic AVRT. The small differences between those intervals are related to the proximity of the RV apical pacing site to the SVT reentry circuit. Larger differences in these intervals are observed in the setting of AVNRT or

Fig. 17.13 Induction of Atrioventricular Node (AVN) Echo Beats by Ventricular Pacing. Note that ventriculoatrial conduction during ventricular pacing is occurring up the slow AVN pathway (red arrows). This results in AVN echo beats caused by anterograde conduction over the fast pathway, which results in occasional QRS fusion (i.e., fusion between the echo beat and the paced impulse) during the pacing drive. Cessation of ventricular pacing is followed by double AVN echo beats (blue arrows). CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; HRA, high right atrium; RVA, right ventricular apex.

administration of atropine, a finding suggesting that the site of block is not in the AVN. In addition, a VES introduced during the 2:1 AV block consistently results in 1:1 conduction, indicating that the AV block is functional and that the level of block is infranodal. Therefore what was previously thought to be 2:1 AVN block in the lower common pathway of the AVN (because of the absence of visible His potentials) is more likely to be intra-Hisian block. VA block during AVNRT rarely has been reported (see Fig. 17.13).

As noted, variations A/V relationship, with or without AV block during tachycardia, should not be misdiagnosed as AT; they can be atypical or, rarely, typical forms of AVNRT. Moreover, the variations could be of such magnitude that a long RP tachycardia can masquerade for brief periods of time as a short RP tachycardia.

Oscillation in the tachycardia cycle length. When CL variability is observed during typical AVNRT, it is generally caused by changes in anterograde conduction over the slow AVN pathway. Because retrograde conduction through the fast pathway generally is much less variable, the changes in the ventricular CL that result from variability in anterograde AVN conduction precede and predict the subsequent changes in the atrial CL (eFig. 17.2), as is the case in orthodromic AVRT.

Effect of bundle branch block. The development of prolonged functional aberration during AVNRT is uncommon, and it usually occurs at initiation of the tachycardia or after resumption of 1:1 AV conduction after a period of block in the HB or lower common pathway (see Fig. 17.9). When bundle branch block (BBB) does occur during AVNRT, it does not influence the TCL (A-A or H-H intervals) because the ventricles are not required for the tachycardia circuit.

Termination and response to physiological and pharmacological maneuvers. The TCL is correlated best with the conduction time down the slow pathway. Spontaneous or pharmacologically mediated changes in the TCL are also more closely associated with changes in slow pathway conduction. Spontaneous termination of typical AVNRT occurs because of a block in the fast or the slow pathway. However, the better the retrograde fast pathway conduction, the less likely it will be the site of the block. Carotid sinus massage and vagal maneuvers can terminate typical AVNRT with gradual anterograde slowing and then block in

the slow pathway, whereas block in the fast pathway in this setting is uncommon.

AVN blockers (digoxin, calcium channel blockers, and beta-blockers) prolong the refractoriness of the fast and slow pathways to similar or different degrees. Such effects mediate termination of AVNRT. However, they can also potentially help dissociate the ERP of the fast and slow pathways and unmask dual AVN physiology and, thus, facilitate inducibility of AVNRT. Adrenergic stimulation tends to shorten the anterograde and retrograde ERP of the fast pathway to a greater extent than that of the slow pathway. Conversely, beta-blockers tend to prolong ERP of the fast pathway more than that of the slow pathway.⁶

Adenosine produces differential effects on anterograde and retrograde conduction over the different AVN pathways. The effect of adenosine is far less potent on retrograde fast pathway conduction than on the retrograde slow pathway and anterograde fast and slow pathway conduction. During slow-fast AVNRT, adenosine can increase the TCL by prolonging the AH interval (i.e., anterograde slow pathway conduction), with little or no change of conduction time and conduction sequence of the retrograde fast pathway. The mechanism of adenosine resistance of retrograde fast pathway conduction (both in patients with slow-fast AVNRT and in normal subjects) remains unclear.⁹

Atypical Atrioventricular Nodal Reentrant Tachycardia

The earliest site of retrograde atrial activation during atypical AVNRT is usually recorded at the base of the triangle of Koch or CS os, and CS breakthrough is observed in most patients. The CS breakthrough is likely part of or very close to the reentry circuit, as demonstrated by entrainment mapping.

The RP interval during atypical fast-slow AVNRT is longer than the PR interval. In addition, the PR and AH intervals are shorter during AVNRT than during NSR (Fig. 17.15).

Usually, the A/V ratio equals 1, as is the case for typical AVNRT. BBB can occur but does not influence the TCL. In contrast to typical AVNRT, CL variability during atypical AVNRT is usually caused by changes in retrograde conduction over the slow AVN pathway. Anterograde conduction occurs over the more stable fast AVN pathway and

Fig. 17.15 Spontaneous Termination of Atypical (Fast-Slow) Atrioventricular Nodal Reentrant Tachycardia (AVNRT). Oscillation of the tachycardia cycle length (CL) is observed just before termination. Note that changes in the atrial CL predict changes in the subsequent ventricular CL because CL variability during atypical AVNRT is usually caused by changes in retrograde conduction over the slow atrioventricular node (AVN) pathway, whereas anterograde conduction occurs over the more stable fast AVN pathway and is less subject to variability. In addition, the PR interval (PRI) and atrial-His bundle interval are shorter during AVNRT than those during sinus rhythm. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; HRA, high right atrium; RVA, right ventricular apex.

eFig. 17.2 Typical Atrioventricular Nodal Reentrant Tachycardia With Right Bundle Branch Block. Intermittent ventriculoatrial block is observed (*arrow*) secondary to block in an upper common pathway. Oscillation of the tachycardia cycle length is observed before the block. Note the changes in the H-H and V-V intervals preceding similar changes in the A-A interval. Both atrial tachycardia and orthodromic atrioventricular reentrant tachycardia are excluded by the fact that the atrium is not necessary for continuation of the tachycardia. *CS_{dist}*, Distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *HRA*, high right atrium; *RVA*, right ventricular apex.

Fig. 17.16 Atrial Extrastimulation During Atrioventricular Nodal Reentrant Tachycardia (AVNRT). An atrial extrastimulation delivered during AVNRT has no effect on the timing of the immediately following His potential ($H-H$ interval = 500 milliseconds) but advances the timing of the next His potential ($H-H$ interval = 460 milliseconds). Arrows mark His potentials. CS_{dist} , Distal coronary sinus; CS_{prox} , proximal coronary sinus; His_{dist} , distal His bundle; His_{mid} , middle His bundle; His_{prox} , proximal His bundle; HRA , high right atrium; RVA , right ventricular apex.

is less subject to variability (see Fig. 17.15). Therefore, during atypical AVNRT, changes in the atrial CL predict changes in the subsequent ventricular CL (as is the case in AT). Carotid sinus massage, vagal maneuvers, adenosine, and AVN blockers (e.g., digoxin, calcium channel blockers, and beta-blockers) generally terminate atypical AVNRT by gradual slowing and then block in the retrograde slow pathway (see Fig. 17.15). Termination of atypical AVNRT with adenosine can also result from block in the fast AVN pathway; however, the value of this observation in distinguishing between atypical AVNRT and orthodromic AVRT using a slow retrograde BT is questionable.

Diagnostic Maneuvers During Tachycardia

Programmed Atrial Stimulation During Tachycardia

Resetting. A late-coupled AES usually fails to reach the AVN with adequate prematurity and thus fails to affect the tachycardia, and a full compensatory pause results. However, the AES can result in concealment in perinodal tissue and, consequently, retard conduction of the impulse traveling retrogradely up the fast pathway and, hence, result in a delay in the timing of the next atrial activation. This is usually manifested by an AES that delays the subsequent atrial activation but without affecting the timing of HB and ventricular activation.

During typical AVNRT, an early-coupled AES frequently penetrates the AVN and resets the reentry circuit, with a resulting compensatory pause that is less than, equal to, or greater than a full compensatory pause, depending on the degree of anterograde conduction delay that the AES encounters down the slow pathway (because of the decremental conduction properties of the AVN). The AES orthodromically propagates through the anterograde slow pathway, with a resulting alteration of the subsequent $H-H'$ interval, whereas it antidromically collides with

the preceding tachycardia wavefront traveling retrogradely up the fast pathway (Fig. 17.16). Progressively more premature AESs encounter progressive anterograde conduction delay in the slow pathway, and an increasing resetting response pattern occurs. In atypical AVNRT, an early-coupled AES can reset the SVT in a fashion similar to that seen in typical AVNRT; however, the delay in conduction that the AES will engender is mainly in the retrograde limb of the circuit (i.e., the slow pathway). Of note, an AES that accelerates the next His potential and resets tachycardia is indicative of focal junctional tachycardia (Fig. 17.17).

Resetting with manifest fusion (a hallmark of macroreentrant tachycardias) cannot be demonstrated in AVNRT. For atrial fusion (i.e., fusion of atrial activation from both the tachycardia wavefront and the AES) to occur, the AES should be able to enter the reentrant circuit, while at the same time the tachycardia wavefront should be able to exit the circuit. This requires spatial separation between the entry and exit sites to the reentrant circuit, a condition that seems to be lacking in the setting of AVNRT. Once the tachycardia wavefront exits the reentry circuit to activate the atrium, any AES delivered beyond that time and resulting in atrial fusion is not capable of reaching the reentry circuit because the entry-exit site is already refractory in response to activation by the exiting wavefront, and the AES has no alternative way of reaching the circuit. Similarly, once an AES is capable of reaching the reentry circuit, the entry and exit site region is made refractory and incapable of allowing a simultaneous exit of the tachycardia wavefront.

During typical AVNRT, a very early-coupled AES can block anterogradely in the slow pathway, and it usually collides with the retrograde wavefront traveling up the fast pathway to terminate the SVT. However, if the TCL is sufficiently long, with a wide fully excitable gap, and the AES is appropriately timed, the AES can block anterogradely in the

Fig. 17.17 Atrial Extrastimulation During Focal Junctional Rhythm. An atrial extrastimulation delivered during focal junctional rhythm advances the timing of the immediately following His potential ($H-H$ interval = 830 milliseconds) and resets the timing of the following His potential ($H-H$ interval = 860 milliseconds). CS_{dist} , distal coronary sinus; CS_{prox} , proximal coronary sinus; His_{dist} , distal His bundle; His_{mid} , middle His bundle; His_{prox} , proximal His bundle; RV , right ventricular.

slow pathway and still conduct down the fast pathway to capture the HB and ventricle and terminate the SVT before the SVT wavefront traveling down the slow pathway reaches the lower turnaround point. Therefore the last HB and ventricular electrograms before termination are advanced and premature, in contrast to termination secondary to an AES blocking anterogradely in the slow and fast pathways, whereby the last HB and ventricular electrograms of the SVT occur on time. This phenomenon occurs more commonly in atypical AVNRT.

During atypical AVNRT, a very early-coupled AES can conduct down the fast pathway during retrograde slow pathway activation and block retrogradely in the slow pathway. In this setting, the AES results in a premature HB and ventricular activation, and the AVNRT is terminated before the expected atrial activation.

Termination. The ability of an AES to terminate AVNRT depends on the following: (1) the TCL (AVNRT with a TCL shorter than 350 milliseconds is rarely terminated by a single AES, unless atrial stimulation is performed close to the AVN); (2) the distance of the site of atrial stimulation from the AVN (which would influence the ability of the AES to arrive to the AVN with adequate prematurity); (3) the refractoriness of the intervening atrial tissue (which can be overcome by delivery of multiple AESs); (4) atrial conduction velocity resulting from the AES; and (5) the size of the excitable gap in the reentrant circuit.

Atrial entrainment. Atrial pacing at a CL approximately 10 to 30 milliseconds shorter than the TCL is usually able to entrain AVNRT. In contrast to orthodromic AVRT, entrainment with atrial fusion cannot be demonstrated during AVNRT, a finding suggesting that the reentrant circuit in AVNRT does not have widely separate atrial entry and exit sites. Therefore, during entrainment of AVNRT by atrial pacing, the

atrial activation sequence and P wave morphology are always similar to those of the pure paced morphology. However, one study showed orthodromic capture of the atrial electrogram at the HB recording site (i.e., the bipolar HB electrogram morphology is identical to that during the tachycardia and is unaffected by pacing, and the first PPI is identical to the PCL) during entrainment from the CS or CS_{prox} region, a finding consistent with intracardiac atrial fusion. This suggests the absence of an upper common pathway between a reentrant circuit and atrial tissue surrounding the AVN and supports the concept that the reentrant circuit in AVNRT incorporates the atrial tissue surrounding the AVN. The AH interval during entrainment is usually longer than that during AVNRT because the atrial and the His electrograms are activated in parallel during AVNRT, and in sequence during atrial pacing entraining the AVNRT (in response to the presence of intervening atrial tissue separating the site of atrial stimulation from the reentry circuit).^{22,23}

Ventriculoatrial linking. The initial atrial complex following cessation of atrial pacing entraining typical AVNRT is *linked* to, and cannot be dissociated from, the last captured ventricular complex (and the last HB activation). As a consequence, postpacing VA intervals are fixed and similar to those during tachycardia (with less than 10 milliseconds variation) after different attempts at atrial entrainment, regardless of the site, duration, or CL of the entraining atrial pacing drive. VA linking is also observed after the introduction of an AES with a wide range of coupling intervals during tachycardia. VA linking occurs in the setting of typical AVNRT because the timing of atrial activation is dependent on activation of the lower turnaround point (and, hence, the HB and ventricular activation) by the last paced atrial impulse before traveling retrogradely up the fast pathway to activate the atrium. VA linking can

also be observed in orthodromic AVRT, whereby atrial activation is always dependent on the preceding ventricular activation. In contrast, in the setting of AT, the first atrial return cycle following cessation of pacing is dependent on the distance between the AT origin and pacing site, the atrial conduction properties, and the mode of the resetting response of the AT, and it is not related to the preceding ventricular activation. Hence, the postpacing VA intervals following different attempts at entrainment can vary especially when pacing at different rates or durations, or from different atrial sites.⁸

Programmed Ventricular Stimulation During Tachycardia

Resetting. For a VES to reset the AVNRT circuit, it needs to advance (prematurely activate) the HB timing by a degree that is dependent on the following: (1) the TCL, (2) the local ventricular ERP, (3) the time needed for the VES to reach the HB, and (4) the length of the lower common pathway. The longer the lower common pathway is, the more the timing of HB activation must be advanced so that the VES will be able to activate the AVNRT circuit prematurely. Therefore, in atypical (fast-slow and slow-slow) AVNRT, which typically has a long lower common pathway, the HB activation must be advanced by more than 30 to 60 milliseconds. Conversely, in typical (slow-fast) AVNRT, the lower common pathway is short or absent, and the tachycardia is typically reset by the VES as soon as the HB activation is advanced.⁸

A late-coupled VES may block in the HPS or lower common pathway and may not affect the SVT (Fig. 17.18A). A late-coupled VES that resets the SVT without first retrogradely activating the HB (i.e., VES delivered before or within 50 milliseconds after the expected inscription of the anterograde His potential) excludes AVNRT (except when a bystander AV BT is present).

An early-coupled VES can reset AVNRT, especially when the TCL is relatively long (>350 milliseconds). The resetting VES antidromically collides with the preceding tachycardia wavefront traveling anterogradely and is conducted through the retrograde pathway to reset the tachycardia (see Fig. 17.18). The resetting of AVNRT with fusion of the QRS cannot be demonstrated because of the shared entry-exit site (i.e., the HB) from the ventricle to the circuit.

Termination. Termination of AVNRT with VES is difficult (more so than termination with AES) and is rare when the TCL is shorter than 350 milliseconds. Such termination favors the diagnosis of orthodromic AVRT. In typical AVNRT, when termination occurs, it is usually caused by block of the VES in the anterograde or retrograde limb of the AVNRT circuit. The slower the SVT is, the more likely the block will be to occur in the anterograde slow pathway. Ventricular pacing can terminate AVNRT more easily than VES because rapid ventricular pacing can modulate and overcome the refractoriness of the intervening HPS. VES always terminates atypical AVNRT by blocking retrogradely in the slow pathway.

Ventricular entrainment. Ventricular pacing at a CL approximately 10 to 30 milliseconds shorter than the TCL is usually able to entrain AVNRT. Visualization of the His potential before atrial activation during entrainment helps differentiate AVNRT from orthodromic AVRT. If the His potential cannot be visualized during ventricular pacing, two other parameters can be helpful to distinguish AVNRT from orthodromic AVRT: the VA interval during ventricular pacing and the PPI.^{22,23}

Δ VA interval. Entrainment of the SVT by RV pacing can help differentiate orthodromic AVRT from AVNRT by evaluating the VA interval during SVT (measured from the onset of surface QRS to the high RA electrogram) versus the VA interval during pacing (i.e., the SA interval, measured from the ventricular pacing stimulus to the high RA electrogram). The ventricle and atrium are activated in sequence during orthodromic AVRT and during ventricular pacing, but in parallel during AVNRT. Therefore the VA interval during orthodromic AVRT

approximates that during ventricular pacing (see Fig. 18.43). In contrast, the VA interval during AVNRT is much shorter than that during ventricular pacing (Figs. 17.19 and 17.20). In general, a difference in the VA interval (Δ VA [$VA_{\text{pacing}} - VA_{\text{SVT}}$]) greater than 85 milliseconds is consistent with AVNRT, whereas a Δ VA of less than 85 milliseconds is consistent with orthodromic AVRT (see Fig. 20.14).^{24,25}

Postpacing interval. The PPI after entrainment of AVNRT from the RV apex is significantly longer than the TCL (the [PPI – TCL] difference is usually >115 milliseconds) because the reentrant circuit in AVNRT (confined above the HB and not involving the ventricle) is far from the ventricular pacing site. In AVNRT, the PPI reflects the conduction time from the pacing site through the RV muscle and HPS, once around the reentry circuit and back to the pacing site. Therefore the difference between the PPI and TCL reflects twice the sum of the conduction time through the RV muscle, the HPS, and the lower common pathway. In orthodromic AVRT using a septal BT, the PPI reflects the conduction time through the RV to the septum, once around the reentry circuit and back to the pacing site. In other words, the difference between the PPI and TCL reflects twice the conduction time from the pacing site through the ventricular myocardium to the reentry circuit. Because the ventricle is an essential component of the AVRT circuit, the RV apex is closer to the tachycardia circuit. Therefore the PPI more closely approximates the TCL in orthodromic AVRT using a septal BT ([PPI – TCL] difference is usually <115 milliseconds) compared with AVNRT. This maneuver was studied specifically for differentiation between atypical AVNRT and orthodromic AVRT using a septal BT, but the principle also applies to typical AVNRT (see Figs. 17.19 and 17.20). For borderline values, ventricular pacing at the RV base can help exaggerate the difference between the PPI and TCL in the setting of AVNRT, but without significant changes in the setting of orthodromic AVRT (see differential-site RV entrainment below).⁸

Importantly, overdrive ventricular pacing during entrainment can induce decremental anterograde AVN conduction. Subtracting the increment in AVN conduction time in the first PPI (postpacing AH interval – prepacing AH interval) from the (PPI – TCL) difference (the so-called “corrected” [PPI – TCL]) has been found to improve the accuracy of this criterion. The difference between the AV intervals (postpacing AV interval – prepacing AV interval) can be taken for the latter adjustment when a clear His deflection is not visible. A corrected (PPI – TCL) of less than 110 milliseconds was found to be highly accurate in identifying orthodromic AVRT as distinct from AVNRT.^{26,27}

Of note, determinations of the corrected (PPI – TCL) and Δ VA ($VA_{\text{pacing}} - VA_{\text{SVT}}$) after resetting with single or double VESs from the RV apex, is of similar value for discrimination between AVNRT and orthodromic AVRT, even when the SVT is interrupted by ventricular pacing. Corrected (PPI – TCL) of more than 110 milliseconds and Δ VA of more than 110 milliseconds after resetting identify AVNRT.²⁸

However, there are several potential pitfalls to those criteria. The TCL and VA interval are often perturbed for a few cycles after entrainment. For this reason, care should be taken not to measure unstable intervals immediately after ventricular pacing. In addition, spontaneous oscillations in the TCL and VA intervals can be seen. The discriminant points chosen may not apply when the spontaneous variability is more than 30 milliseconds. Furthermore, it is possible to mistake isorhythmic VA dissociation for entrainment if the pacing train is not sufficiently long or the PCL is too close to the TCL. Finally, those criteria may not apply to BTs with significant decremental properties, although small decremental intervals are unlikely to provide a false result.²⁹

Manifest ventricular fusion. No QRS fusion is manifest during ventricular entrainment of AVNRT, and QRS morphology is that of pure paced morphology. Fusion during resetting or entrainment of AVNRT with ventricular stimulation would require the paced ventricular

Fig. 17.18 Resetting of Atrioventricular Nodal Reentrant Tachycardia (AVNRT) With Ventricular Extrastimulation (VES) at Different Coupling Intervals. (A) Late-coupled VES delivered when the His bundle is refractory fails to reset the AVNRT. In fact, the anterograde His potential (*H*) is visualized shortly after the pacing artifact (*arrows*), occurring at the expected timing (the tachycardia cycle length is indicated by the *red lines*). (B) An early VES delivered well before the expected time of the anterograde His potential fails to reset the tachycardia. The fact that this VES advances ventricular activation at all recorded sites by approximately 70 milliseconds and still fails to reset the tachycardia excludes orthodromic atrioventricular reentrant tachycardia. (C) Earlier VES results in resetting of the supraventricular tachycardia, as indicated by earlier timing of the following atrial activation. Double arrows indicate the H-H interval during tachycardia. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; HRA, high right atrium; RVA, right ventricular apex.

wavefronts to enter the circuit propagating through the HB at the time that impulses are exiting through this structure. The HB is also the site of exit of the tachycardia circuit to the ventricular tissue. Therefore collision of the antidromic wavefront and the orthodromic wavefront from the preceding beat occurs in AVN tissue and not in the ventricle. Under

such circumstances, constant fusion during entrainment is impossible (unless a second connection exists between the atria and ventricles; i.e., an innocent bystander BT). Manifest ventricular fusion during entrainment of SVT indicates that the reentrant circuit includes ventricular tissue (diagnostic of AVRT), thus excluding both AVNRT and AT.^{22,23}

Fig. 17.19 Entrainment of Typical Atrioventricular Nodal Reentrant Tachycardia (AVNRT) With Ventricular Pacing. Pacing is performed from the right ventricular apex (RVA). The postpacing interval minus tachycardia cycle length (PPI – TCL) is more than 115 milliseconds, and the Δ VA interval ($VA_{\text{pacing}} - VA_{\text{SVT}}$) is more than 85 milliseconds. The atrial activation sequence during ventricular pacing is identical to that during AVNRT. No QRS fusion is observed. Cessation of ventricular pacing is followed by an A-V electrogram sequence. CS_{dist} , distal coronary sinus; CS_{prox} , proximal coronary sinus; HRA, high right atrium; PCL, pacing cycle length; SVT, supraventricular tachycardia; VA, ventriculoatrial.

Fig. 17.20 Entrainment of Atypical Atrioventricular Nodal Reentrant Tachycardia (AVNRT) With Ventricular Pacing. Pacing is performed from the right ventricular apex (RVA). The postpacing interval minus tachycardia cycle length (PPI – TCL = 172 milliseconds) is long, and the Δ VA interval ($VA_{\text{pacing}} - VA_{\text{SVT}} = 188$ milliseconds) is also long; both criteria favor AVNRT over orthodromic atrioventricular reentrant tachycardia. Note that the atrial activation sequence during RV pacing is similar to that during the SVT, again favoring AVNRT over other types of SVT. In addition, a pseudo-A-A-V electrogram sequence is observed following cessation of ventricular pacing because retrograde conduction occurs through the slow pathway during ventricular pacing with a long VA interval (red arrows), longer than the pacing cycle length (PCL); hence, the last ventricular paced impulse is followed first by the P wave conducted slowly from the previous paced QRS and then by the P wave resulting from the last paced QRS, thus mimicking an A-A-V electrogram sequence. This is confirmed by the observation that the last atrial activation resulting from conduction of the last paced ventricular complex follows the preceding P wave with an A-A interval equal to the ventricular PCL. CL, Cycle length; CS_{dist} , distal coronary sinus; CS_{prox} , proximal coronary sinus; HRA, high right atrium; SVT, supraventricular tachycardia; VA, ventriculoatrial.

Differential-site RV entrainment. Differential-site RV entrainment (from RV apex vs. RV base) can help distinguish AVNRT from orthodromic AVRT. Because the reentrant circuit in AVNRT is confined above the HB and does not involve the ventricle, the base of the RV is electrically more distant (although anatomically closer) to the tachycardia circuit than the RV apex, given that the His-Purkinje network directly inserts in the RV apex. Consequently, the PPI after entrainment

of AVNRT from the RV base is longer than that following entrainment from the RV apex. The difference in PPI from the RV base versus the RV apex is largely composed of the extra time required to reach the circuit from the base versus the apex (approximately 30 milliseconds). Conversely, in orthodromic AVRT, in which the ventricles are an obligatory part of the circuit, the basal pacing site relative to the RV apex is variably related to the circuit, closer than the RV apex with septal BTs

and equidistant with free wall BTs, but the paced wavefront from either the RV apex or the RV base tends to have, on average, approximately equal access and proximity to the reentrant circuit involved in orthodromic AVRT. Therefore the time taken to reach the circuit (and hence the PPI) tends to be similar, irrespective of the location of the BT.

As noted, decremental conduction can occur during entrainment of either AVNRT or orthodromic AVRT, and most commonly it occurs during conduction through the AVN, especially the AVN slow pathway. The degree of decrement is dependent on both the pacing rate and the functional refractory properties of the AVN. Therefore the PPI will prolong if decrement occurs, but the degree of decrement is not expected to be materially different from basal rather than apical pacing, as long as the pacing rates are the same or similar. To avoid potential error introduced by decremental conduction within the AVN, correction of the PPI is preferred, and it is obtained by subtracting any increase in the AV interval of the return cycle beat (compared with the AV interval during SVT). In one study, a differential corrected (PPI – TCL) of more than 30 milliseconds after transient entrainment was observed in all cases of AVNRT (i.e., corrected PPI following pacing from the RV base was consistently at least 30 milliseconds longer than that following pacing from the RV apex), and corrected (PPI – TCL) of less than 30 milliseconds was observed in all cases of orthodromic AVRT. In addition, differential VA interval (SA interval during entrainment from RV base vs. RV septum) of more than 20 milliseconds was consistent with AVNRT, whereas a differential VA interval of less than 20 milliseconds was consistent with orthodromic AVRT.³⁰

Length of pacing drive required for entrainment. Careful analysis of the beginning of RV pacing during the SVT can help differentiate orthodromic AVRT from AVNRT. In the setting of orthodromic AVRT, ventricular tissue is the only intervening tissue between the pacing wavefront and the ventricular insertion site of the BT. Therefore, once ventricular capture is achieved during RV pacing, the paced wavefront propagates to the ventricular insertion site of the BT quickly and resets the tachycardia. Consequently, RV pacing results in a faster response of resetting the tachycardia. On the other hand, during AVNRT, the paced wavefront has to penetrate the HPS and AVN tissue prior to resetting the tachycardia. This results in delayed resetting of the tachycardia compared with orthodromic AVRT. After initiation of synchronized RV pacing during SVT at a PCL 10 to 40 milliseconds shorter than the TCL, once constant-appearing paced RV complexes (either pure capture or fixed fusion) are observed (as evidenced by fixed pacing morphology of the surface ECG), the number of RV paced beats required to accelerate the atrial CL to the PCL is determined. The first controlled atrial beat (accelerated to the PCL) is identified by demonstrating a fixed SA interval. One report demonstrated that using a cutoff of one beat to accelerate the atria to the PCL could identify all orthodromic AVRT cases and essentially exclude all cases of AVNRT with high accuracy. When two or more beats are required to accelerate the atria to the PCL, AVNRT is favored over orthodromic AVRT (see Fig. 20.13).³¹

Atrial resetting during the transition zone. On initiation of RV pacing trains during SVT at a rate slightly faster than the TCL, there is a transition zone during which the pacing train fuses with anterograde ventricular activation (i.e., the zone in which the paced QRS complexes show progressive fusion with the SVT complexes) until a stable QRS morphology is observed (either completely paced or constantly fused). In patients with AVNRT or AT, acceleration of the timing of atrial activation cannot occur through the AVN during the transition zone. The reason is that the HB is expected to be refractory, as indicated by at least some ventricular activation still occurring by anterograde conduction over the HPS, similar to the concept of entrainment with manifest fusion discussed previously. If perturbation of atrial timing occurs during

the transition zone, it indicates the presence of a retrogradely conducting BT, which can be an integral part of the SVT circuit (i.e., orthodromic AVRT) or a bystander. In one report, these criteria showed excellent diagnostic accuracy and could be applied regardless of whether entrainment was achieved or whether the SVT terminated during pacing. Perturbation of atrial timing for 15 milliseconds or longer or a fixed SA interval measured from the last beat of the transition zone was seen in all the patients with orthodromic AVRT and in none of the patients with AVNRT or AT (unless a bystander retrogradely conducting BT is present).³²

Atrial and ventricular electrogram sequence following cessation of ventricular pacing. Following ventricular entrainment of typical AVNRT, an “A-V” electrogram sequence is observed after the last paced QRS (see Fig. 17.19). In contrast, following overdrive ventricular pacing (1:1 VA conduction) during AT, retrograde conduction occurs through the AVN. In this setting, the last retrograde P wave resulting from ventricular pacing is unable to conduct back to the ventricle because the AVN is still refractory to anterograde conduction, and the result is an A-A-V response (as discussed in detail in Chapter 20). Importantly, this maneuver is not useful when 1:1 VA conduction during ventricular pacing is absent (see Fig. 11.17). In addition, a pseudo-A-A-V response can occur during atypical AVNRT because retrograde conduction during ventricular pacing occurs through the slow pathway. This can result in a VA interval that is longer than the PCL; hence, the last ventricular paced impulse is followed first by the P wave conducted slowly from the previous paced QRS and then by the P wave resulting from the last paced QRS, thus mimicking an A-A-V response (see Fig. 17.20). Careful identification of the last atrial electrogram that resulted from VA conduction during ventricular pacing avoids this potential pitfall. The last atrial activation resulting from conduction of the last paced ventricular complex follows the preceding P wave with an A-A interval equal to the ventricular PCL. A pseudo-A-A-V response can also occur during typical AVNRT with long HV intervals or short HA intervals, or both, in which atrial activation precedes ventricular activation. In the latter setting, using HB activation instead of ventricular activation (i.e., characterizing the response as A-A-H or A-H instead of A-A-V or A-V, respectively) can be more accurate and can help eliminate misinterpretation of the pseudo-A-A-V response.³³

Para-Hisian Pacing During Tachycardia

Overdrive para-Hisian pacing during the SVT helps exclude the presence of a septal AV BT, which can mediate an orthodromic AVRT with a retrograde atrial activation sequence similar to that during AVNRT (discussed in detail in Chapter 20).

During SVT, para-Hisian pacing is performed at a PCL 10 to 30 milliseconds shorter than the TCL. Responses to this maneuver are then classified as (1) entrainment: when the atrial CL is accelerated to the PCL, without a change in the atrial activation sequence, and the tachycardia resumes after pacing is discontinued; (2) termination: when pacing results in termination of the tachycardia; and (3) AV dissociation: when HB capture is confirmed and no change in the atrial CL is observed.

Because the HB is a necessary component for the circuit in AVRT, overdrive capture of the HB during AVRT should result in immediate entry into the tachycardia (manifesting as either entrainment or termination of the SVT). In contrast, HB overdrive pacing during AVNRT may not immediately enter the circuit because the HB is not an obligate component. Therefore entry into the tachycardia circuit within one beat indicates AVRT, whereas entry into the circuit occurring only after three or more beats is consistent with AVNRT.³⁴

Furthermore, para-Hisian entrainment of the SVT is performed by alternately pacing at high-energy output for HB-RB capture or lower

energy output for HB-RB noncapture. Entrainment with HB-RB capture is recorded separately from that without HB-RB capture. The SA and local VA intervals during HB-RB capture and noncapture are then examined. If para-Hisian entrainment cannot be performed because of repetitive termination of the tachycardia during pacing attempts, single or double VESs can be given to reset the tachycardia (para-Hisian resetting). These VESs are delivered at progressively shorter coupling intervals until the first VES that reliably advances or resets the tachycardia. This is performed alternately with high- or low-energy outputs to achieve HB-RB capture and noncapture, respectively. As with para-Hisian entrainment, the retrograde atrial activation sequence and timing are compared during para-Hisian resetting to characterize the response.³⁵

In AVNRT (typical or atypical), the AVN-AVN pattern is observed in response to para-Hisian entrainment or resetting; that is, both the SA and the local VA intervals increase during HB-RB noncapture compared with HB-RB capture. Conversely, in orthodromic AVRT, the BT-BT pattern or BT-BT_L pattern is observed (see Chapter 20 for detailed discussion).

A Δ SA interval of less than 40 milliseconds was found to be a reasonable guide for separating the AVN-AVN from the BT-BT response. Patients with AVNRT uniformly have a Δ SA interval of greater than 40 milliseconds, whereas those with AVRT have a Δ SA interval of less than 40 milliseconds (except for rare patients with a left lateral BT). Using the Δ local VA interval (instead of Δ SA interval) provides a more accurate parameter for discrimination between AVNRT and AVRT.

Diagnostic Maneuvers During Sinus Rhythm After Tachycardia Termination

When pacing the atrium or ventricle at the TCL, it is important that the autonomic tone be similar to its state during the tachycardia because alterations of autonomic tone can independently influence AV or VA conduction.

Atrial Pacing at the Tachycardia Cycle Length

The difference in the AH interval between atrial pacing (at the TCL) and SVT can allow differentiation of fast-slow AVNRT from other types of long RP tachycardias. A Δ AH ($AH_{\text{pacing}} - AH_{\text{SVT}}$) greater than 40 milliseconds has been reported to favor AVNRT. In contrast, during AT and orthodromic AVRT using a septal BT, the AH interval during SVT approximates that during atrial pacing and, thus, a Δ AH of less than 20 milliseconds favors AT and orthodromic AVRT. This has only been tested with RA pacing during right ATs and should be applied with caution when a left AT is suspected.⁸

The Δ AH ($AH_{\text{pacing}} - AH_{\text{SVT}}$) can also help differentiate typical (slow-fast) AVNRT from AT with a long PR interval. Atrial pacing during NSR at the TCL yields an AH interval that is similar to that during AT but shorter than the AH interval during typical AVNRT. During atrial pacing in patients with AT, AV conduction occurs preferentially conduction over the fast pathway and, hence, is expected to be associated with similar AH and PR intervals (under equivalent autonomic tone). In contrast, AV conduction during typical AVNRT occurs over the slow pathway, resulting in a long AH interval.

Ventricular Pacing at the Tachycardia Cycle Length

Δ HA interval. Ventricular pacing at the TCL results in HA and VA intervals that are longer during pacing than those during AVNRT when assessed with standard 5 mm spacing quadripolar catheters in the HB position. With more closely spaced HB recording electrodes, the HA interval during pacing (HA_{pacing}) can be less than that during tachycardia (HA_{SVT}), a finding implying that part of the proximal HB is part of the AVNRT circuit (i.e., absence of a lower common pathway). Whether or not the HA interval during pacing is longer than that during tachy-

cardia thus depends in large part on how proximal an HB recording is made. The Δ HA interval ($HA_{\text{pacing}} - HA_{\text{SVT}}$) is typically more than -10 milliseconds because the HA interval during AVNRT is shortened by parallel activation of both the HB and the atrium during the tachycardia (i.e., the HA interval is a “pseudo-interval” that represents activation times of the HB and atrium), whereas the HB and atrium are activated sequentially during ventricular pacing (i.e., the HA interval represents a true conduction time interval from the HB to the atrium; Fig. 17.21). The Δ HA interval is even more pronounced in atypical AVNRT, which has a lower common pathway that is longer than that in typical AVNRT. This is in contrast to orthodromic AVRT, in which HA_{pacing} is shorter than HA_{SVT} because the HB and atrium are activated sequentially during orthodromic AVRT but in parallel during ventricular pacing (the atrium is activated via the BT). As a result, the Δ HA interval in the setting of orthodromic AVRT is typically less than -10 milliseconds.¹¹ The Δ HA criterion can only be used when (1) retrograde conduction during ventricular pacing occurs over the same pathway as during SVT and (2) one can discern a retrograde HB potential during ventricular pacing.

Ventriculoatrial block. Under comparable autonomic tone, 1:1 VA conduction over the AVN may or may not be maintained during ventricular pacing at the TCL because of possible retrograde block in

Fig. 17.21 His Bundle-Atrial (HA) Interval During Tachycardia Versus Ventricular Pacing. HA intervals (marked by dashed lines) during atrioventricular nodal reentrant tachycardia (AVNRT; left) and ventricular pacing at tachycardia cycle length in the same patient (right), measured from His potential onset to onset of atrial activation (near CS_{prox}). Notice that the HA interval is shorter during AVNRT than that during pacing because the atrium and His bundle are activated in parallel during AVNRT but in sequence during ventricular pacing. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; His_{dist}, distal His bundle; His_{mid}, middle His bundle; His_{prox}, proximal His bundle; HRA, high right atrium; RVA, right ventricular apex.

the lower common pathway. Anterograde conduction properties of the lower common pathway may allow 1:1 conduction from the AVNRT circuit down to the ventricle, but its retrograde conduction properties may not allow 1:1 VA conduction during ventricular pacing at a PCL similar to the TCL. Thus the presence of VA block during ventricular pacing favors AT and AVNRT with lower common pathway physiology over orthodromic AVRT.

Atrial activation sequence. The atrial activation sequence during ventricular pacing is usually (but not necessarily) similar to that during AVNRT. A different atrial activation sequence suggests the presence of a retrogradely conducting BT (which may or may not be related to the SVT), but also can be observed in AVNRT when the retrogradely conducting AVN pathway during AVNRT is different from that used during ventricular pacing.

Exclusion of Other Arrhythmia Mechanisms

Other tachycardia mechanisms (orthodromic AVRT, AT, and focal junctional tachycardia) can mimic AVNRT, and should be excluded. Several maneuvers can help with the differential diagnosis. However, it is important to note that limitations exist to all diagnostic maneuvers, and assessment of the response to multiple different pacing maneuvers in determining the mechanism of SVT should be considered, rather than relying upon a single maneuver.

Atrial Tachycardia

Focal ATs arising from the anterosseptal region can mimic typical AVNRT, and those originating from the right or left posteroseptal region can mimic atypical AVNRT. The various EP testing maneuvers used to exclude these tachycardias are outlined in [Box 17.3](#).

Atrioventricular Reentrant Tachycardia

Orthodromic AVRT using superoparaseptal BTs or posteroseptal BTs can mimic typical or atypical AVNRT, respectively. Several maneuvers can help distinguish between the two arrhythmias ([Box 17.4](#)).

Focal Junctional Tachycardia

Focal junctional tachycardia (also known as “nonparoxysmal,” “non-reentrant,” or “ectopic” junctional tachycardia) originates from the AV junction (encompassing the AVN and HB). Junctional tachycardia is rare in adults, and is encountered more frequently in children. It occurs mainly as a transient arrhythmia following cardiac surgery, most likely a result of ischemic injury to the cardiac conduction system during cardiopulmonary bypass, which is exacerbated by the use of sympathomimetic agents in the early postoperative period. In addition, junctional tachycardia can be associated with digoxin toxicity and myocardial ischemia. Rarely, paroxysmal or incessant junctional tachycardia can be observed, with a presentation similar to that of focal AT. The mechanism of junctional tachycardia is likely related to enhanced automaticity, but abnormal automaticity and triggered activity also can play a role in some patients.

ECG features of junctional tachycardia. Junctional tachycardia can manifest as a regular narrow QRS tachycardia with a short RP interval and retrograde P waves, mimicking typical AVNRT. Junctional tachycardia can also present as an irregular narrow QRS tachycardia with retrograde conduction block and intermittent AV dissociation (often isorhythmic), mimicking multifocal AT or AF. On the other hand, VA block is often observed, resulting in SVT with intermittent AV dissociation (often isorhythmic). When associated with aberrant conduction and wide QRS complex, junctional tachycardia can mimic VT, particularly if VA conduction is absent.

The differentiation of AVNRT from junctional tachycardia is of clinical importance because ablation of the latter is associated with an

BOX 17.3 Exclusion of Atrial Tachycardia

Oscillations in TCL

- Changes in atrial CL that are predicted by changes in the preceding ventricular CL argue against AT.
- Spontaneous changes in TCL accompanied by constant VA interval (VA linking) exclude AT.

SVT Induction by AES

- “Critical AH” required for SVT induction favors AVNRT over AT.
- If the VA interval of the first tachycardia beat is reproducibly identical to that during the rest of the SVT (“VA linking”), AT is very unlikely.

VES During SVT

- VES that terminates the SVT without atrial activation excludes AT.
- VES that delays the next atrial activation excludes AT.

Overdrive Ventricular Pacing During SVT

- The presence of A-V electrogram sequence following cessation of pacing is consistent with AVNRT and generally excludes AT.
- Atrial activation sequence during pacing similar to that during the SVT favors AVNRT over AT.

Overdrive Atrial Pacing During SVT

- ΔAH interval ($AH_{\text{pacing}} - AH_{\text{SVT}} > 40$ ms favors AVNRT over AT.
- If the VA interval following the last entrained QRS is reproducibly constant (with <10 ms variation), despite pacing at different CLs or for different durations (VA linking) and similar to that during TCL, AT is unlikely.
- If the VA interval following the last entrained QRS is reproducibly constant (with <14 ms variation), despite pacing at different atrial sites (VA linking), AT is unlikely.

SVT Termination

- Reproducible termination of the SVT (spontaneous or in response to adenosine or vagal maneuvers) with a P wave not followed by a QRS excludes AT, except in the case of a nonconducted PAC terminating the AT.

Atrial Pacing During NSR at TCL

- ΔAH interval ($AH_{\text{pacing}} - AH_{\text{SVT}} > 40$ ms excludes AT.
- AV block during atrial pacing (under similar autonomic tone) argues against AT.

AES, Atrial extrastimulation; AH, atrial–His bundle; AT, atrial tachycardia; AV, atrioventricular; A-V, atrium–ventricle; AVNRT, atrioventricular nodal reentrant tachycardia; CL, cycle length; NSR, normal sinus rhythm; PAC, premature atrial complex; SVT, supraventricular tachycardia; TCL, tachycardia cycle length; VA, ventriculoatrial; VES, ventricular extrastimulus.

increased risk of AV block.⁸ AV dissociation, when present, excludes the AVRT and makes AVNRT highly unlikely. Bursts of short RP tachycardia without initiation by PACs or PR prolongation are more consistent with junctional tachycardia rather than AVNRT.

EP features of junctional tachycardia. The EP hallmark of junctional tachycardia is the presence of a His potential preceding the QRS complex. The HV interval is typically normal, but can be prolonged in the setting of distal HPS disease.

Unlike AVNRT, junctional tachycardia is nonreentrant, and cannot be induced or terminated by programmed stimulation. Initiation of the tachycardia is usually spontaneous (and often requires isoproterenol administration), with the absence of a critical AH delay ([Box 17.5](#)). In addition, junctional tachycardia is characterized by a gradual increase in tachycardia rate (warm-up) following initiation, marked CL variation,

BOX 17.4 Exclusion of Orthodromic Atrioventricular Reentrant Tachycardia**VA Interval During SVT**

- VA interval <70 ms or a V–high RA interval <95 ms during SVT excludes orthodromic AVRT.

AV Block During SVT

- Spontaneous or induced AV block with continuation of the SVT excludes orthodromic AVRT.

VES During the SVT

- Failure to reset (advance or delay) atrial activation with early-coupled VES on multiple occasions and at different VES coupling intervals, despite advancement of the local ventricular activation at all sites (including the site of the suspected BT) by >30 ms, excludes orthodromic AVRT and the presence of AV BT.
- Δ VA interval ($VA_{\text{pacing}} - VA_{\text{SVT}}$) >110 ms (after resetting with single or double VESs from the RV apex) argues against AVRT.
- Corrected (PPI – TCL) >110 ms (after resetting with single or double VESs from the RV apex) argues against AVRT.
- When a VES resets the SVT without atrial activation (i.e., the VES advances the subsequent His potential and QRS), orthodromic AVRT is excluded.

Entrainment of SVT by Ventricular Pacing

- Δ VA ($VA_{\text{pacing}} - VA_{\text{SVT}}$) >85 ms argues against orthodromic AVRT.
- PPI – TCL >115 ms (or corrected [PPI – TCL] >110 ms) argues against orthodromic AVRT.
- Acceleration of the SVT to the PCL occurring only after ≥ 2 beats with stable paced QRS morphology is consistent with AVNRT and argues against orthodromic AVRT.
- Differential corrected PPI – TCL of >30 ms after transient entrainment from the RV apex versus the RV base is consistent with AVNRT and argues against orthodromic AVRT.
- Differential VA interval (SA interval during entrainment from RV base versus RV septum) of >20 ms is consistent with AVNRT and argues against orthodromic AVRT.

Entrainment of SVT by Atrial Pacing

- Δ AH interval ($AH_{\text{pacing}} - AH_{\text{SVT}}$) of >40 ms favors AVNRT over orthodromic AVRT.

Para-Hisian Entrainment or Resetting

- Prolongation of the SA and the local VA intervals on loss of HB capture, compared with that during HB capture is consistent with AVNRT and argues against orthodromic AVRT.
- The change in the stimulus to earliest atrial activation time (Δ SA interval) with loss of HB–RB capture >40 ms is consistent with AVNRT and argues against orthodromic AVRT.
- Entry into the tachycardia circuit (manifesting as resetting, entrainment, or termination of the SVT) occurring only after three or more beats is consistent with AVNRT and argues against orthodromic AVRT.

Ventricular Pacing During NSR at the TCL

- Δ HA ($HA_{\text{pacing}} - HA_{\text{SVT}}$) >–10 ms is consistent with AVNRT and argues against orthodromic AVRT.

Atrial Pacing During NSR at the TCL

- Δ AH ($AH_{\text{pacing}} - AH_{\text{SVT}}$) >40 ms is consistent with AVNRT and argues against orthodromic AVRT.

Differential RV Pacing During NSR

- Pacing at the RV base producing a longer VA (SA) interval and identical atrial activation sequence compared with that during pacing at the RV apex excludes the presence of a septal AV BT mediating an orthodromic AVRT.

Para-Hisian Pacing During NSR

- Loss of HB RB capture resulting in an increase in the SA interval in all electrograms (equal to the increase in the S–H interval), with no change in the atrial activation sequence or HA interval, excludes the presence of a septal AV BT mediating an orthodromic AVRT.

AH, Atrial–His bundle interval; AV, atrioventricular; AVNRT, atrioventricular nodal reentrant tachycardia; AVRT, atrioventricular reentrant tachycardia; BT, bypass tract; CL, cycle length; HA, His bundle–atrial; HB, His bundle; NSR, normal sinus rhythm; PPI, postpacing interval; RA, right atrium; RB, right bundle branch; RV, right ventricle; SA, stimulus-to-atrial; S–H, stimulus-to-His bundle; SVT, supraventricular tachycardia; TCL, tachycardia cycle length; VA, ventriculoatrial; VES, ventricular extrastimulation.

BOX 17.5 Exclusion of Focal Junctional Tachycardia**Tachycardia Induction**

- Spontaneous initiation of the tachycardia (with or without isoproterenol) with absence of a critical AH delay is consistent with junctional tachycardia.
- Failure of tachycardia inducibility with programmed electrical stimulation favors junctional tachycardia.

Tachycardia Features

- Incessant tachycardia is consistent with junctional tachycardia and practically excludes AVNRT.
- AV dissociation favors junctional tachycardia over AVNRT.

AES During SVT

- An early AES (delivered prior to HB depolarization) that advances the His potential immediately after it without terminating the tachycardia is consistent with junctional tachycardia.
- An AES (delivered from the proximal CS) timed to HB refractoriness that either terminates or resets the tachycardia the His potential of the subsequent cycle effectively excludes junctional tachycardia and confirms a diagnosis of AVNRT.

Overdrive Atrial Pacing During SVT

- An “H–H–A” response following cessation of overdrive atrial pacing (with 1:1 AV conduction) during SVT is consistent with junctional tachycardia, whereas an “H–A” response favors AVNRT.
- An AH interval during atrial pacing that is significantly shorter than AH interval during SVT is consistent with junctional tachycardia.
- Dissociation of atrial activation from HB activation during atrial pacing is consistent with junctional tachycardia.

Overdrive Ventricular Pacing During SVT

- Zero or positive Δ HA interval ($HA_{\text{pacing}} - HA_{\text{SVT}}$) is consistent with junctional tachycardia.
- Negative Δ HA interval is consistent with AVNRT.

AES, Atrial extrastimulation; AH, atrial–His bundle; AV, atrioventricular; AVNRT, atrioventricular nodal reentrant tachycardia; CS, coronary sinus; HA, His bundle–atrial; HB, His bundle; SVT, supraventricular tachycardia.

Fig. 17.22 Automatic Junctional Tachycardia. First beat to the left is sinus, followed by spontaneous, unprovoked onset of junctional tachycardia. Notice the first beat of the tachycardia starts with a His potential (*H*) and is not preceded by any trigger. The tachycardia rate accelerates (warms up). Conduction to the ventricle is maintained, but 2:1 ventriculoatrial block develops at faster tachycardia rate (*arrows*), as well as right bundle branch block aberrancy. *A*, Atrial electrogram; *CS_{dist}*, distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *HRA*, high right atrium; *RVA*, right ventricular apex.

and slow decrease in tachycardia rate (cool-down), rather than an abrupt termination (Fig. 17.22).⁸

When junctional tachycardia is associated with aberrant conduction and AV dissociation, it becomes important to differentiate the tachycardia from VT. The His potential with anterograde propagation (i.e., proximal to distal His) preceding the QRS by a normal or prolonged HV interval largely excludes myocardial and fascicular VT.

Atrial extrastimulation. An early AES (delivered prior to HB depolarization) that advances the His potential immediately after it without terminating the tachycardia indicates that the retrograde fast pathway is not essential for the circuit and is consistent with junctional tachycardia (see Fig. 17.17). For such an AES to advance the immediately following His potential (with a short AH interval), it has to be conducted over the AVN fast pathway. In the setting of AVNRT, conduction of the AES over the fast pathway (which constitutes the retrograde limb of the typical slow-fast AVNRT circuit) would render that pathway refractory to further participation in AVNRT and, hence, AVNRT would be terminated (Fig. 17.23). In typical AVNRT, an early AES can conduct anterogradely only over the slow pathway and, hence, it can do so only with a long AH interval and can affect not the immediate His potential but only the subsequent one (see Fig. 17.16).^{8,36}

An AES (delivered from the proximal CS) timed to HB refractoriness that either terminates or resets the tachycardia (i.e., delays or advances the His potential of the subsequent cycle) effectively excludes junctional tachycardia and confirms a diagnosis of AVNRT (see Fig. 17.23). In this maneuver, the timing of HB activation is a surrogate marker for the time when the retrograde AVN fast pathway is refractory; hence, for an AES to be able to influence the subsequent His timing, the presence of an AVN slow pathway is required to mediate anterograde conduction of the AES.^{8,37–39} Rarely, a patient with junctional tachycardia has an anterograde slow AVN pathway that can be used to advance the timing of the subsequent HB activation, falsely suggesting AVNRT. However, the next HB activation cannot be delayed in this situation.

Atrial pacing during tachycardia. Following overdrive atrial pacing (with 1:1 AV conduction) during tachycardia, HB and atrial electrogram sequence can help distinguish AVNRT from junctional tachycardia. Atrial overdrive pacing is performed from the high RA or CS at a PCL 20 to 30 milliseconds shorter than TCL until the His potential is advanced to the PCL, at which point pacing is terminated. Upon resumption of the tachycardia, the first return electrogram after the last advanced His potential is examined.

Atrial overdrive pacing during junctional tachycardia transiently suppresses the arrhythmia focus, with immediate resumption of the tachycardia following the cessation of pacing. As a result, the first return electrogram will be a junctional beat preceded by a His potential that travels retrogradely over the AVN to activate the atrium, resulting in an “H-H-A” response. In contrast, an “H-A” electrogram sequence after the last paced atrial complex is consistent with typical AVNRT, whereby the last paced will conduct anterogradely over the slow pathway and exit the AVN into the HB while echoing retrogradely up the fast pathway, to activate the atrium.^{11,38,40,41}

Importantly, a pseudo-H-H-A response is commonly observed during typical AVNRT. Because anterograde conduction during atrial pacing occurs through the slow pathway, the AH interval is long and can be longer than the PCL (A-A interval), so that the last paced atrial beat is followed first by the HB electrogram resulting from slow AV conduction of the preceding paced atrial beat and then by the HB electrogram resulting from the last paced atrial beat. In other words, the atrial pacing spike typically precedes the His potential and QRS that were advanced from the previous atrial paced beat. Hence, after cessation of pacing, the immediate His potential is the result of the one before the last atrial paced beat, with the subsequent His potential being the one advanced from the last atrial paced beat, resulting in a pseudo H-H-A response. To avoid this potential pitfall, the H-H intervals should be measured during and after atrial overdrive pacing and the last His potential resulting from AV conduction during atrial pacing is carefully examined.

Fig. 17.23 Tachycardia Response to Early- and Late-Premature Atrial Complex (PAC). *Left panel*, Tachycardia response to early-coupled PACs. (A) Response in junctional tachycardia (JT): Solid circles represent junctional focus. Black lines show conduction through atrioventricular node (AVN), His (H), and atrium (A). Red arrow indicates PAC. Open circle represents the anticipated JT beat timing if no PAC were delivered. An early PAC advances the immediate JT beat and His timing by AVN fast pathway (FP) activation and JT continues. (B) Response in atrioventricular nodal reentrant tachycardia (AVNRT): an early PAC may advance the immediate His by activation of the AVN FP. However, that makes the FP refractory and unavailable for retrograde conduction, terminating the AVNRT circuit. Red arrow indicates PAC and its response. *Right panel*, Tachycardia response to late-coupled PACs. The PAC is delivered when AV junction is refractory (local atrial activation from PAC occurs at or after His activation). (C) Response in JT: a PAC delivered at a time the AV junction focus has already depolarized blocks at the AVN and is unable to influence the immediate or the next junction beat. (D) Response in AVNRT: a similarly timed PAC can influence the next beat of AVNRT by early engagement of the slow pathway (SP). Although this figure shows advancement of the next beat ($x-n$), delay of the next beat or termination of tachycardia are also specific to AVNRT. X and $x-n$ = H-H intervals. (From Padanilam BJ, Manfredi JA, Steinberg LA, Olson JA, Fogel RI, Prystowsky EN. Differentiating junctional tachycardia and atrioventricular node re-entry tachycardia based on response to atrial extrastimulus pacing. *J Am Coll Cardiol*. 2008;52:1711–1717.)

The last advanced His potential characteristically occurs at an H-H interval equal to the atrial PCL, whereas the first tachycardia His potential usually occurs at a longer return CL. The atrial and HB electrogram sequence following this last advanced His potential should be noted. If an atrial electrogram follows, an H-A response is diagnosed; if a His potential follows, an H-H-A response is diagnosed.⁴¹

Of note, the paced AH interval can be helpful in differentiating junctional tachycardia from typical AVNRT. The paced AH interval during atrial overdrive pacing of AVNRT is longer than the paced AH interval during atrial overdrive pacing of junctional tachycardia. During atrial overdrive pacing of AVNRT, anterograde AV conduction uses only the slow pathway because the fast pathway (which is used as the retrograde limb of the reentry circuit) is refractory from retrograde conduction. In contrast, during atrial overdrive pacing of junctional tachycardia, anterograde AV conduction is mediated by the fast pathway.

In addition, dissociation of atrial activation from HB activation can frequently be demonstrated with atrial pacing during junctional tachycardia. Such an observation is inconsistent with AVNRT.

Ventricular pacing during tachycardia. Zero or positive Δ HA interval (i.e., HA interval during RV pacing minus HA interval during tachycardia, $HA_{\text{pacing}} - HA_{\text{SVT}}$) has been reported to indicate junctional tachycardia. During both junctional tachycardia and RV pacing, the HA interval represents the true time interval of impulse conduction from the HA to the atrium. In contrast, the HA interval during AVNRT is a “pseudo-interval,” representing the relative activation timing of the HB and atrium, and the value of the HA interval depends on the presence and length of the lower common pathway. Hence, the Δ HA interval in AVNRT is negative (averaging about -10 milliseconds). However,

difficulty in obtaining a clear His signal with RV pacing limits the utility of this maneuver.³⁸

Management of junctional tachycardia. In general, data regarding the management of junctional tachycardia is limited, and mostly has been reported in pediatric literature. Pharmacologic therapy offers modest efficacy. While about two-thirds of patients experience partial improvement, complete suppression of the arrhythmia is achieved in only a minority of patients. Beta-blockers are often used as first-line chronic therapy for junctional tachycardia. Alternative medications include verapamil, diltiazem, flecainide, propafenone, and procainamide. The efficacy of amiodarone has been reported only in pediatric patients. The value of digoxin has not been well established.¹⁴

Catheter ablation may be reasonable in patients with junctional tachycardia and offers success rates of more than 80%. However, in view of the reported 5% to 10% risk of AV block, catheter ablation is generally reserved for highly symptomatic patients in whom drug therapy has been ineffective or not tolerated. Cryoablation has a significant safety advantage in these patients.¹⁴ Catheter ablation typically targets the focus of the tachycardia. When VA conduction is intact during junctional tachycardia, the site of earliest atrial activation serves as the initial target for ablation. If this fails, or if VA conduction is absent, then sequential empiric lesions can be applied in the posterior septum (the slow AV nodal pathway region), the mid-septum, and the anterior septum, incurring higher risks of permanent AV block. Occasional patients have isolated junctional premature complexes (that must be distinguished from PACs); these may be highly symptomatic and may warrant ablation therapy if medical treatment is unsuccessful.

ABLATION

Ablation of the slow AVN pathway is indicated in patients with SVT and documented AVNRT during EP testing, but it also can be performed in patients with documented SVT that is morphologically consistent with AVNRT on a preprocedure ECG or rhythm strip but in whom only dual AVN physiology (but not tachycardia) is demonstrated during an EP study. Slow pathway ablation also may be considered at the discretion of the physician when sustained (>30 seconds) AVNRT is induced incidentally during an ablation procedure directed at a different clinical tachycardia.

Target of Ablation

The slow pathway is the target of ablation for all variants of AVNRT. Initially, the rightward inferior AVN extension is targeted. Then, the leftward inferior AVN extension is targeted if needed. Rarely, ablation of the inferolateral left atrial pathway can be necessary.

Historically, the initial approach of RF ablation of AVNRT was modification of AVN conduction by the energy application near the anterosuperior aspect of the triangle of Koch (fast pathway ablation or the “anterior approach”). However, because the fast pathway constitutes the physiological anterograde conduction axis and is located in close proximity to the compact AVN and HB, this procedure was associated with an unacceptable risk of AV block or unphysiologically long PR intervals (which can cause symptoms similar to those of the pacemaker syndrome), and was consequently abandoned. In addition, in patients with multiple slow pathways, ablation of the fast pathway can be associated with persistently inducible AVNRT with anterograde conduction over a second slowly conducting pathway. Since the early 1990s, selective ablation of the AVN slow pathway by lesions created near the postero-inferior base of the triangle of Koch between the CS os and tricuspid annulus (the “posterior approach”) has proved to be a more successful and safer procedure. Unlike fast pathway ablation, successful ablation of the slow pathway can eliminate all variants of AVNRT.

However, selective slow pathway ablation can be particularly challenging in certain clinical situations. For example, in patients with evidence of impaired fast pathway conduction (usually older patients with TCL >400 milliseconds), ablation of the slow pathway can result in mandatory conduction through the impaired fast pathway, and Wenckebach block during rest can develop. Whether the fast pathway should be targeted for ablation instead of the slow pathway in these patients is controversial. Similarly, some patients with AVNRT have a markedly prolonged PR interval during NSR, a finding that suggests the possibility of absent anterograde fast pathway conduction and a high risk of complete AV block if the slow pathway is ablated. On the other hand, the fast pathway in such patients can be affected by an electrotonic interaction with the slow pathway, and elimination of this effect by slow pathway ablation often shortens the ERP of the fast pathway. In fact, in many of these patients, the AH interval remains stable or even shortens after slow pathway ablation.¹⁷

The site of the slow pathway to be targeted by ablation can be defined by one of two approaches: a purely anatomic approach and an electroanatomic approach. Despite the lack of precise knowledge of the pathophysiological substrate for AVNRT, ablation procedures have fortunately been very successful.

Anatomic Approach

The sequence of ablation sites chosen for RF delivery is related to the probability of successful slow pathway ablation at each site and the risk of impairing AV conduction. The most common site for effective and safe ablation is the location of the rightward inferior AVN extension at the isthmus of tissue between the tricuspid annulus and the CS os

(Fig. 17.24); ablation at this site has a success rate of 95%. Occasionally, successful ablation can require the catheter positioned along the tricuspid annulus inferior to the CS os or at the floor of the CS os. If those sites are unsuccessful, RF delivery is attempted at the roof of the proximal CS (1 to 3 cm from the CS os), the site of leftward inferior AVN extension. Rarely, successful slow pathway ablation can require ablation on the left side of the posterior atrial septum, along the mitral annulus (the site of inferolateral left atrial pathway). Successful ablation sites in this region typically exhibit an A/V ratio of 1:10 to 1:2. If ablation at all of these sites is unsuccessful, RF delivery may be considered at more cephalad sites along the tricuspid annulus superior to the upper edge of the CS os (presumably near the junction of the leftward and rightward inferior extensions), closer to the compact AVN, but only if the risk of complete AV block can be justified by the severity of clinical symptoms.

Electroanatomic Approach

The electroanatomic approach is guided by the identification of slow pathway potentials in conjunction with anatomic landmarks. These potentials have been used by some investigators to define the site of the slow pathway within the triangle of Koch, and they can be used as a guide to target ablation.

It has been suggested that activation of the slow pathway is associated with inscription of discrete electrical potentials, often referred to as slow pathway potentials. The origin of these potentials is uncertain. Whether they represent nodal tissue activation, anisotropic conduction through muscle bundles in various sites in the triangle of Koch, or a combination of both, remains unclear. The electrogram morphology of the slow potentials has been variously described as sharp and rapid (representing the atrial connection to the slow pathway; see Fig. 17.24), or slow and broad with low amplitude (representing slow potentials; see Fig. 17.24). The timing of slow potentials during NSR was reported to follow closely (within 10 to 40 milliseconds) local atrial activation near the CS os, or span the AH interval (it can occur as late as the His potential). This activation sequence is reversed during AVNRT (i.e., slow pathway potential precedes the atrial electrogram). However, such potentials are not specific to the triangle of Koch or to patients with AVNRT, and they can be recorded near the tricuspid annulus at sites distant from the slow pathway. Despite these observations, the probability of recording putative slow potentials at the site of effective slow ablation is more than 90%.

For ablation of atypical (slow-slow and fast-slow) AVNRT, the slow pathway used by the reentry circuit for retrograde conduction is targeted by ablation, and this target can be different from the AVN slow pathway used for anterograde conduction. Therefore ablation can be guided by the site of earliest retrograde atrial activation during atypical AVNRT, which is usually localized to the isthmus of tissue between the tricuspid annulus and the CS os in fast-slow AVNRT and along the anterior aspect of the CS in slow-slow AVNRT (Fig. 17.25).

Importantly, in the setting of typical (slow-fast) AVNRT, the site with the earliest atrial activation during tachycardia should not be targeted by mapping and ablation, since this location is often at the fast pathway exit site and ablation can cause AV block.^{11,42} It is also important to know that in some cases of typical slow-fast AVNRT, the fast pathway can have a more posterior location, and the earliest atrial activation site during the tachycardia is near the CS os. In such cases, ablation should be performed with caution because RF application at the usual slow pathway anatomic site can result in PR interval prolongation or heart block. Cryoablation can be an advantage in these situations.

Ablation Technique

For slow pathway ablation, a quadripolar, 4-mm-tip, deflectable ablation catheter is advanced through a femoral vein. Rarely, an SVC approach

Fig. 17.24 Ablation of Atrioventricular Nodal Reentrant Tachycardia (AVNRT). *Upper panel*, Right anterior oblique (RAO) and left anterior oblique (LAO) fluoroscopic views of a typical catheter setup during AVNRT ablation. The ablation catheter (ABL) is positioned at the slow pathway location in the lower portion of the triangle of Koch, away from the His bundle (His) and anterior to the coronary sinus (CS) (those landmarks are defined by the His bundle and CS catheters, respectively). *Lower panel*, Intracardiac recordings during ablation of the slow pathway. Note the sharp (blue arrow, left lower panel) and broad (red arrow, right lower panel) potentials recorded between the atrial and ventricular electrograms at the ablation sites. Those potentials were suggested to reflect activation of the slow pathway (slow pathway potentials). ABL_{dist}, Distal ablation bipole; CS_{dist}, distal coronary sinus; CS_{prox}, proximal coronary sinus; His_{dist}, distal His bundle; His_{mid}, middle His bundle; His_{prox}, proximal His bundle; HRA, high right atrium; RVA, right ventricular apex.

(through the internal jugular or subclavian vein) is required because of IVC obstruction or barriers, and one report demonstrated the feasibility of this approach. Large-tip and irrigated-tip catheters have no role in catheter ablation of the slow pathway because the larger lesions they create can increase the risk of AV block, and the superficial location of AVN tissue does not require large or deep lesions.⁴²

Anatomic Approach

The anatomic approach is based on targeting the anatomic landmarks of the slow pathway. As noted, the target of slow pathway ablation is

the isthmus of tissue between the tricuspid annulus and the CS os. Using the right anterior oblique (RAO) fluoroscopy view, which best displays the triangle of Koch in profile, the ablation catheter is advanced into the RV, moved inferiorly so that it lies anterior to the CS os, and then withdrawn until the distal pair of electrodes records small atrial and large ventricular electrograms (with an A/V electrogram amplitude ratio during NSR of 1:10 to 1:2). Gentle clockwise torque is maintained to keep the catheter in contact with the low atrial septum. This positions the catheter along the tricuspid annulus immediately anterior to the CS os (see Fig. 17.24). Positioning is best performed during NSR,

Fig. 17.25 Ablation Target in Atypical (Fast-Slow) Atrioventricular Nodal Reentrant Tachycardia (AVNRT). Ablation is guided by the site of earliest retrograde atrial activation during atypical fast-slow AVNRT, which is usually localized to the isthmus of tissue between the tricuspid annulus and the CS os. A small spike (arrows) precedes the earliest atrial electrogram. *ABL_{dist}*, Distal ablation bipole; *ABL_{prox}*, proximal ablation bipole; *CS os*, coronary sinus ostium; *CS_{dist}*, distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *His_{dist}*, distal His bundle; *His_{mid}*, middle His bundle; *His_{prox}*, proximal His bundle; *HRA*, high right atrium; *RVA*, right ventricular apex.

rather than AVNRT, because the atrial and ventricular electrograms at the tricuspid annulus are more easily discerned. The catheter often slips into the CS when one applies even a small amount of torque because the CS is large in many of these patients. If the catheter does not easily reach far enough into the ventricle, yielding an A/V ratio of only 1:1, or if catheter stability is inadequate or falls into the CS repeatedly, a long sheath with a slight septal angulation can be helpful. Moreover, some ablation catheters have asymmetrical bidirectional deflection curves, an option that can prove to be of value for catheter reach and stability in some cases.⁴²

Electroanatomic Approach

The target site is identified by slow pathway potentials (see Fig. 17.24). Initially, the triangle of Koch is mapped from the apex (where the HB is recorded) and then moved toward the CS os. This approach also helps evaluate the extension of the zone recording a His potential. Slow pathway potentials are usually recorded at the mid-anterosseptal position, where they are located in the middle of the isoelectric line connecting the atrial and ventricular electrograms. Moving the mapping catheter inferiorly, the slow pathway potential moves toward the atrial electrogram, and when the optimal site for slow pathway ablation is reached, it merges with the atrial electrogram. Because electrograms with these characteristics can be recorded near the tricuspid annulus at sites distant from the slow pathway, the region explored with the ablation catheter should be limited to the posterior septum, near the

CS os. In the left anterior oblique (LAO) fluoroscopy view, using the HB and CS os positions (as defined by the HB and CS catheters) as landmarks, the most common area where the slow potentials are recorded is in the posterior third of the line connecting those two landmarks.

Validation of slow pathway potentials can be useful and can be achieved by demonstrating that they represent slow and decremental conduction properties. Typically, brief runs of incremental atrial pacing or AES produce a decline in the amplitude and slope, an increase in the duration, and a separation of the slow potential from the preceding atrial electrogram until disappearance of any consistent activity. This is especially helpful in the presence of a sharp slow pathway potential, to distinguish it from a proximal HB recording (eFig. 17.3). Catheter-induced junctional ectopy, when resulting from catheter pressure in this area, as opposed to the HB, indicates that the catheter tip is at a good ablation site. In patients with slow-slow and slow-fast AVNRT, mapping during AVNRT often shows a discrete potential 20 to 40 milliseconds prior to the earliest atrial electrogram; this may indicate the slow pathway and signify a good target site.

Radiofrequency Energy Delivery

Catheter stability should be optimized before starting RF energy application to help avoid inadvertent AV block. This can require the use of long, preshaped sheaths and the cessation of isoproterenol infusion if hyperdynamic contractility is present. In addition, good positioning of the other EP catheters defining the anatomic landmarks demarcating

eFig. 17.3 Slow Pathway Potential. A putative slow pathway potential (*blue arrows*) is validated as being distinct from the His bundle potential (*red arrows*) by a burst of atrial stimulation. *ABL_{dist}*, Distal ablation bipole; *ABL_{prox}*, proximal ablation bipole; *CS_{dist}*, distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *His_{dist}*, distal His bundle; *His_{mid}*, middle His bundle; *His_{prox}*, proximal His bundle; *HRA*, high right atrium; *RVA*, right ventricular apex; *S*, stimulus.

the triangle of Koch and the location of HB is mandatory. During RF application, catheter position should be continuously monitored with fluoroscopy or a real-time 3-D mapping system.

Ablation should be performed during NSR, when it is easier to maintain a stable catheter position. When ablation is carried out during AVNRT, sudden termination of the tachycardia during RF delivery can potentially result in dislodgment of the ablation catheter, inadvertent AV block, or an incomplete RF lesion.

Typical RF settings consist of a maximum power of 50 W and a maximum temperature of 55°C to 60°C, continued for 30 to 60 seconds, or until the junctional rhythm extinguishes (see later). Impedance and ECG should be carefully monitored throughout RF application. However, in the case of slow pathway ablation, the decrement in impedance associated with successful energy applications is usually small (approximately 2.5 Ω); such a small change precludes the clinical usefulness of impedance monitoring as an indicator of a successful RF application.

Junctional Rhythm

An accelerated junctional rhythm typically develops within a few seconds of RF delivery at the effective ablation site (Fig. 17.26). The mechanism of this rhythm is unclear but is likely secondary to enhanced automaticity in AVN tissue because of thermal injury. Accelerated junctional rhythm during RF ablation is usually associated with subtle differences in the retrograde atrial activation sequence (compared to that during AVNRT). Occurrence of this rhythm is strongly correlated with successful ablation sites; it occurs more frequently (94% vs. 64%) and for a longer duration (7 vs. 5 seconds) during successful compared with unsuccessful RF applications. However, junctional rhythm is not specific for slow pathway ablation and is routinely observed during intentional fast pathway and AVN ablation. More rapid junctional tachycardia, on the other hand, is probably caused by thermal injury of the HB and heralds impending AV block (Fig. 17.27).^{42,43}

When an accelerated junctional rhythm occurs, careful monitoring of VA conduction during this rhythm is essential, and overdrive atrial pacing may be performed to ensure the maintenance of 1:1 anterograde AV conduction (see Fig. 17.26). Occasionally, atrial pacing at a rate sufficiently fast to override the junctional rhythm results in AV Wencke-

bach block at baseline, even before the onset of RF energy delivery. In this case, isoproterenol may be used to shorten the AV block CL and maintain 1:1 AV conduction during pacing.⁴⁴

The absence of junctional rhythm during RF application usually corresponds to an unsuccessful ablation site. When an accelerated junctional rhythm does not develop within 10 to 20 seconds of RF delivery, RF application should be stopped, and the catheter tip should be repositioned to a slightly different site or until better contact is verified, and a new RF application is attempted. Nevertheless, a junctional rhythm may not occur in several situations, including atypical forms of AVNRT (fast-slow and slow-slow) and some cases of typical (slow-fast) AVNRT undergoing repeat ablation.

After an RF application that results in an accelerated junctional rhythm, programmed electrical stimulation (atrial and ventricular stimulation) is performed to determine the presence or absence of slow pathway conduction, AVN echoes, and tachycardia inducibility. If the result is unsatisfactory, the ablation catheter is moved to a slightly different site, and RF energy is reapplied. After several RF applications that do not elicit junctional rhythm, testing for inducibility of AVNRT or dual pathways should be performed; in rare cases, the slow pathway has been eliminated despite the lack of junctional rhythm, and additional RF applications are not only unnecessary but also potentially hazardous.

Several observations should prompt immediate discontinuation of RF application, including: (1) a sudden impedance rise (more than 10 Ω); (2) prolongation of the PR interval (during NSR or atrial pacing); (3) the development of AV block; (4) a fast junctional tachycardia (CL shorter than 350 milliseconds); and (5) a retrograde conduction block during junctional ectopy (see Fig. 17.27). Although the last observation can herald anterograde AV block in the case of typical AVNRT and necessitates immediate discontinuation of RF delivery, the absence of retrograde conduction over the fast pathway is a common occurrence in patients with atypical AVNRT, even before ablation. In this setting, the occurrence of junctional rhythm with no VA conduction may not be such an ominous sign; in fact, such an occurrence can indicate successful ablation of the slow pathway and thus should prompt ongoing RF delivery. As noted earlier, atrial pacing at a rate sufficient to overdrive

Fig. 17.26 Catheter Ablation of the Atrioventricular Node Slow Pathway. Radiofrequency (RF) energy delivery during normal sinus rhythm results in accelerated junctional rhythm with intact ventriculoatrial conduction. Overdrive atrial pacing at a rate faster than the junctional rhythm rate was started and confirmed intact atrioventricular conduction. This observation can indicate a good ablation site, with no injury to the fast pathway. ABL_{dist}, distal ablation bipole; CS_{dist}, distal coronary sinus; CS_{prox}, proximal coronary sinus; HRA, high right atrium; RVA, right ventricular apex.

Fig. 17.27 Junctional Rhythm During Atrioventricular Node Slow Pathway Ablation. Radiofrequency energy delivery during normal sinus rhythm results in junctional tachycardia. Wenckebach ventriculoatrial (VA) block is observed during the junctional rhythm, a sign that heralds injury to the His bundle and should prompt immediate termination of RF application. *ABL_{dist}*, Distal ablation bipole; *CS_{dist}*, distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *His_{dist}*, distal His bundle; *His_{prox}*, proximal His bundle; *RVA*, right ventricular apex.

junctional rhythm allows the monitoring of anterograde fast pathway conduction and helps to ensure safe RF application.⁴⁴

Endpoints of Ablation

Elimination of Slow Pathway Conduction

The optimal endpoint for slow pathway ablation is the complete elimination of slow pathway conduction and dual AVN physiology without impairing the fast pathway. This is evidenced by loss of conduction over the slow pathway (i.e., disappearance of discontinuous AV conduction curves), alteration of Wenckebach CL (shorter or longer), an increase in the ERP of the AVN, and preservation of intact anterograde and retrograde AVN (fast pathway) conduction. In many cases, the ERP of the fast pathway can actually shorten, which is likely secondary to the withdrawal of electrotonic inhibition imposed on the fast pathway by the slow pathway.¹⁷

Noninducibility of Tachycardia

Elimination of all evidence of slow pathway conduction is not a necessary requirement for a successful slow pathway ablation procedure. It suffices to eliminate the inducibility of AVNRT and 1:1 anterograde conduction over the slow pathway, with and without isoproterenol infusion. Complete elimination of all anterograde slow conduction is not essential for clinical success and is actually associated with a slightly higher risk of AV block. In patients with a successful slow pathway ablation procedure, 40% to 50% will still have dual AVN physiology, and 75% of those patients will have single AVN echoes, but AVNRT is not inducible (these patients are said to have undergone slow pathway modification). In most patients who no longer have inducible AVNRT after ablation in the slow pathway region, residual discontinuous AVN function curves and single AVN echoes do not predict an increased risk of AVNRT recurrence.⁴⁵

Therefore noninducibility of AVNRT (with and without isoproterenol infusion), with residual evidence of dual AVN pathways (AH interval jump) and single AVN echoes with an echo zone shorter than 30 milliseconds, is an acceptable endpoint. However, double AVN echoes or single echoes produced over a wide range of coupling intervals usually predict inducibility of AVNRT with the addition of isoproterenol or atropine, as well as late clinical recurrence of SVT.

When AVNRT or dual AVN physiology is poorly inducible at baseline, it may not be possible to confirm the efficacy of RF ablation. In this setting, other parameters can be indicative of a successful ablation, including the disappearance of a PR/RR ratio greater than 1 during rapid atrial pacing with 1:1 AV conduction, prolongation of the Wenckebach CL, and a decrease in fast pathway ERP.

If isoproterenol was required for initiation of SVT prior to ablation, isoproterenol should be discontinued during ablation and readministered afterward to assess the efficacy of ablation adequately. If isoproterenol was not necessary for SVT initiation prior to ablation, it need not be used for postablation testing. However, if the presence of single AVN echoes is accepted as an endpoint, isoproterenol infusion is then required during postablation testing to verify noninducibility of double echoes or AVNRT.

Reassessment of tachycardia inducibility is typically repeated 30 minutes after the last successful RF application. However, there are no data supporting the hypothesis that such a waiting period leads to reduced recurrence rates following acutely successful ablation. In fact, one report demonstrated that a procedure-prolonging waiting period may be omitted without compromising the patient's long-term outcome results.

Ventriculoatrial Block

Unlike patients with slow-fast AVNRT, those with atypical (slow-slow or fast-slow) AVNRT frequently lack retrograde conduction over the fast pathway even before ablation. In these patients, achievement of complete VA block during ablation indicates the elimination of retrograde conduction over all slow pathways. This endpoint is associated with less arrhythmia recurrence.

Outcome

Acute success rates of AVNRT ablation are approximately 97% to 99%, and they are similar whether the ablation is guided anatomically or electroanatomically. The recurrence rate after apparently successful ablation is approximately 2% to 5%. In 40% of patients with AVNRT recurrences, slow pathway conduction recovers after initial evidence of its abolition. Most AVNRT recurrences take place within the first days to months after ablation.

Atrioventricular Block

The most important complication of AVNRT ablation is AV block, which occurs in approximately 0.2% to 0.8% of patients. AV block generally develops during RF delivery or within the first 24 hours after ablation, and is almost always preceded by junctional ectopy with VA block. The level of AV block is usually in the AVN. Predictors of AV block include proximity of the anatomic ablation site to the compact AVN, the occurrence of fast junctional tachycardia (CL <350 milliseconds) during RF application, the occurrence of junctional rhythm with VA block, the number of RF applications (related to the amount of tissue damage), and significant worsening of anterograde AV conduction during the ablation procedure.

Of note, AV block occasionally develops unexpectedly, even when selective slow pathway ablation is performed at the inferior aspect of the triangle of Koch. This may be related to direct damage to the compact AVN, injury to the right coronary artery or AVN artery, or direct damage to a posteriorly located fast pathway.¹² Sometimes, transient AVN block develops as a result of mechanical trauma during manipulation of the ablation catheter. This may indicate the presence of a relatively small compact AVN that may be more susceptible to heart block during ablation. Catheter-induced AV block typically resolves after seconds to minutes. Careful catheter positioning to avoid sites at which catheter-induced block occurs generally results in successful ablation without AV block.^{5,44}

The development of AV block requiring pacemaker implantation late after the procedure is relatively low (0.4% over 10 years), but remains greater than that observed in patients with other SVTs and in the general population. Late development of AV block can potentially be related to subclinical AVN injury during the procedure that contributes to the accelerated degeneration of AVN function over time, or to the continuing healing process of the RF lesion leading to fibrosis and extension of the lesion size. Of note, the occurrence of even transient AV block during the ablation procedure, especially in older patients, was found to be a marker for the development of AV block requiring pacemaker implantation late after the procedure.⁴⁶

Palpitations

Palpitations occur in 20% to 30% of patients following ablation of AVNRT. These are generally transient and usually are not caused by recurrent AVNRT. Most are caused by PACs or PVCs, which subside spontaneously and require no treatment other than reassurance. Inappropriate sinus tachycardia can develop in some patients after AVNRT ablation, a finding that suggests disruption of the parasympathetic or sympathetic inputs into the sinus node and AVN.

Other Complications

Other procedural complications include cardiac tamponade (in 0.2% of patients), hematoma (0.2%), and femoral artery pseudoaneurysm (0.1%). In addition, subclinical activation of the coagulation system (e.g., elevated plasma levels of the D-dimer) is common during RF ablation. Nevertheless, clinically detectable embolic events are uncommon (0.7%). Treatment with aspirin may be considered for 6 to 8 weeks following ablation, to minimize the risk of thrombus formation in the RA or vena cavae.

Cryoablation of the Slow Pathway

Target of Cryoablation

The target of ablation is the region of the slow pathway, identified anatomically or electroanatomically, as described for standard RF ablation. The target site should be identified during NSR whether cryoablation is to be performed during NSR or AVNRT because the A/V ratio and electrogram morphology usually are obscured during AVNRT.

Cryoablation Technique

Cryomapping. Cryomapping (ice mapping) is designed to verify that ablation at the chosen site will have the desired effect (i.e., block in the slow pathway) and to reassure the absence of complications (i.e., AV block). Cryomapping is performed at a temperature of -30°C . At this temperature, the “test cryolesion” is reversible (for up to 60 seconds), and the catheter is stuck to the atrial endocardium within an ice ball that includes the tip of the catheter (cryoadherence). Formation of an ice ball at the catheter tip and adherence to the underlying myocardium are signaled by the appearance of electrical noise recorded from the ablation catheter’s distal bipole. In the cryomapping mode, the temperature is not allowed to drop to less than -30°C , and the duration of energy application is limited to 60 seconds. Once an ice ball is formed, various pacing protocols are performed to test the modification or disappearance of slow pathway conduction.⁴⁷

Cryomapping is usually performed during NSR in patients with discontinuous anterograde dual AVN conduction curve. For patients without a clear discontinuity in the AVN conduction curve, cryomapping may be performed during AVNRT, which is feasible without the risk of catheter dislodgment on termination of the tachycardia (because of cryoadherence).

During cryoablation of the slow pathway, junctional rhythm is not observed. Thus other parameters must be used to validate the potential effectiveness of the ablation site. In fact, the absence of junctional rhythm can be advantageous because it allows the maintenance of NSR during ablation and enables monitoring of the PR interval throughout the procedure. In addition, the maintenance of NSR during cryoablation allows various pacing maneuvers to be performed during ongoing cryoenergy application, to evaluate the effect of the ablation on slow pathway conduction. The disappearance of dual AVN physiology, the noninducibility of AVNRT, and the modification of the fast pathway ERP predict a successful ablation site. When cryoablation is performed during AVNRT, progressive AH interval lengthening followed by termination of AVNRT indicates slow pathway block.^{47,48}

Slow pathway block usually occurs quickly (within 10 to 20 seconds) at the optimal target site. If cryomapping does not yield the desired result within 20 to 30 seconds or causes unintended AV conduction delay or block, the cryomapping procedure is interrupted. After a few seconds, to allow the catheter to thaw and become dislodged from the tissue, the catheter is moved to a different site, and cryomapping is repeated.

Cryoablation. When sites of successful cryomapping are identified by demonstrating satisfactory slow pathway block or modification with no impairment of the basal anterograde AV conduction, the cryoablation mode is activated, whereby a target temperature lower than -75°C is sought (a temperature of approximately -75°C to -80°C is generally achieved). The application is then continued for 4 minutes, to create an irreversible lesion. If the catheter tip is in close contact with the endocardium, a prompt drop in catheter tip temperature should be seen as soon as the cryoablation mode is activated. A slow decline in temperature or a very high flow rate of refrigerant during ablation suggests poor catheter tip tissue contact; in such cases, cryoablation should be interrupted and the catheter repositioned.^{47,48}

Once a successful cryolesion is achieved, applying one or two additional (“bonus”) cryolesions at the same site can potentially further increase the lesion size and help reduce the risk of tachycardia recurrence. At the successful ablation site, ablation is typically continued for two or three consecutive freeze-thaw cycles of 4 minutes each (total of 12 minutes cryoablation). After rewarming the catheter tip to the body temperature, the next freezing cycle is started immediately without moving the catheter tip away from the successful ablation site. Bonus lesions are not recommended if transient PR interval prolongation or AV block was observed during the first application.^{47,48}

The successful site for cryomapping and cryoablation of the slow pathway frequently is found in the midseptal region of the Koch triangle, more superiorly than the usual site of successful RF ablation. On rare occasions, AV block does not appear during cryomapping at a particular site but develops during cryoablation at the same site. Fortunately, this resolves quickly if the cryoablation is interrupted promptly.

Endpoints of Cryoablation

The goal of cryoablation is the complete elimination of slow pathway function. This usually requires delivery of several cryoapplications at closely adjacent sites. If a discontinuity in the anterograde AVN conduction curve and single AVN echoes persist despite multiple cryoapplications, this is still a reasonable endpoint, provided that multiple AVN echoes or AVNRT are not inducible, even during isoproterenol infusion. If acute procedural success cannot be achieved with a standard 4-mm-tip catheter, a 6-mm-tip catheter can be used, which can help yield larger and deeper cryolesions.^{47,48}

Outcome of Cryoablation

Previously published reports with cryoablation of AVNRT in pediatric patients demonstrated acute procedural success rates of 83% to 100% and recurrence rates ranging from 3% to 20%. Recurrences seem to be less common in the younger patient population. Although the use of bonus cryoapplications to consolidate the acutely successful cryoablation and the choice of larger-tip cryocatheters (8 mm and 6 mm vs. 4 mm tips) to create larger lesions have been associated with fewer long-term recurrences without compromising safety, the overall procedural success rate has remained consistently lower than that of RF ablation. In a meta-analysis of cryoablation versus RF ablation for AVNRT, cryoablation was associated with a lower risk of permanent AV block (0% vs. 0.75%) but a higher risk of long-term AVNRT recurrence (9.7% vs. 3.8%) and longer total procedure time (111.7 minutes vs. 81.2 minutes).^{47–50}

The safety of cryoablation is indisputable. Not a single case of persistent AV block has been reported, even when using large-tip cryocatheters, and despite the fact that transient AV block occurs in up to 2% to 23% of patients during cryomapping at -30°C or during cryoablation at -75°C .

Rarely, transient AV block is observed shortly following the ablation procedure (within the first 24 hours), despite normal AV conduction during cryoablation and at the end of the procedure. The mechanism of late AV block is unclear, especially given the fact that, in contrast to RF ablation, cryoenergy leads to a more limited and well-circumscribed fibrosis, without any signs of chronic inflammation.⁵¹

Advantages of Cryoablation

One of the distinct advantages of cryothermal technology is the ability to demonstrate loss of function of tissue with cooling reversibly (ice mapping or cryomapping), thereby demonstrating the functionality of prospective ablation sites without inducing permanent injury. Furthermore, once the catheter tip temperature is reduced to less than 0°C , progressive ice formation at the catheter tip causes adherence to the adjacent tissue (cryoadherence), which maintains stable catheter contact at the site of ablation and minimizes the risk of catheter dislodgment during changing cardiac rhythm.^{47,48}

Cryoablation can be of particular advantage in patients with AVNRT with posterior displacement of the fast pathway or AVN, and those with a small space in the triangle of Koch between the HB and the CS os, when ablation must be performed in the midseptum. However, given the high success rate and low risk of RF slow pathway ablation, it may be difficult to demonstrate a clinical advantage of cryoablation over RF ablation of unselected AVNRT cases. Therefore the use of cryo-

ablation may be recommended in specific circumstances in which the use of RF can be more likely to cause AVN damage. These circumstances include patients with unusual cardiac anatomy that makes safe RF delivery difficult, those with evidence of impaired AV conduction at baseline, those who need ablation in the close vicinity of the compact AVN following unsuccessful RF ablation at more posterior sites, pediatric patients, and patients in whom even the small risk of AV block associated with RF ablation is considered unacceptable.

TYPES OF BYPASS TRACTS

Bypass tracts (BTs) are remnants of the atrioventricular (AV) connections caused by incomplete embryological development of the AV annuli and failure of the fibrous separation between the atria and ventricles. There are several types of BTs, according to the structures they connect, including AV, atrionodal, atrio-Hisian, atriofascicular, fasciculoventricular, and nodofascicular BTs.¹

Atrioventricular Bypass Tracts

AV BTs are strands of working myocardial cells connecting atrial and ventricular myocardium across the electrically insulating fibrofatty tissues of the AV junction bypassing the atrioventricular node (AVN)-His-Purkinje

system (HPS). In the older literature, these BTs were called Kent bundles, although incorrectly (Kent described AVN-like tissue in the right atrial [RA] free wall that did not connect to the ventricle). Thus the use of the term *bundle of Kent* should be discouraged.

Atrionodal Bypass Tracts

Atrionodal BTs connect the atrium to the distal or compact AVN. They have been called James fibers and are of uncertain physiological significance.

Atrio-Hisian Bypass Tracts

Atrio-Hisian BTs connect the atrium to the His bundle (HB); these BTs are rare.

Atypical Bypass Tracts

The term “atypical BTs” is used here to describe variants of BTs that connect the atrium (atriofascicular BTs), AVN (nodofascicular and nodoventricular BTs), or HB (fasciculoventricular BTs) to distal Purkinje fibers or ventricular myocardium. In addition, this term encompasses slowly conducting short AV BTs and long AV BTs. Although many of those variants of BTs are sometimes referred to as “Mahaim fibers,” it is more appropriate to describe them based on their anatomic connections.

TYPES OF PREEXCITATION SYNDROMES

Several patterns of preexcitation can occur, depending on the anatomy of the BT and the direction in which impulses are conducted. Conduction from the atria to the ventricles normally occurs via the AVN-HPS. Patients with preexcitation have an additional or alternative pathway, the BT, which directly connects the atria and ventricles and bypasses the AVN. The term *syndrome* is used when the anatomical variant is responsible for tachycardia.

Wolff-Parkinson-White Syndrome

In the Wolff-Parkinson-White (WPW) syndrome, AV conduction occurs, partially or entirely, through an AV BT, which results in earlier activation (preexcitation) of the ventricles than if the impulse had traveled through the AVN.

Concealed Bypass Tracts

Concealed AV BTs refer to AV BTs that do not manifest anterograde conduction and therefore do not result in ventricular preexcitation. Because they do not result in alteration of the QRS complex in the electrocardiogram (ECG), they cannot be detected by inspection of the surface ECG; they are called *concealed*. However, the concealed BT can conduct in a retrograde fashion, thereby creating a reentrant circuit with impulses traveling from the atrium to the AVN, HPS, ventricle, and then back to the atrium via the BT.

Lown-Ganong-Levine Syndrome

In the setting of Lown-Ganong-Levine (LGL) syndrome, preexcitation purportedly occurs via atrio-Hisian BTs or, alternatively, no BT is present and enhanced AVN conduction accounts for the ECG findings. The net effect is a short PR interval without delta wave or QRS prolongation. It is important to stress, however, that LGL is not a recognized syndrome with an anatomical basis, but only an ECG description, and the use of the term should be discouraged.

Mahaim Variant of Preexcitation

The so-called Mahaim variant of preexcitation does not typically result in a delta wave because these pathways, which usually terminate in the

conducting system or in the ventricular myocardium close to the conducting system, conduct slowly, and the AVN-HPS has adequate time to activate most of the ventricular muscle mass.

It is worth noting that some of the older literature refers to eponymous pathways that were originally anatomically described with subsequent attempts made to correlate these structures with physiologic findings. With more recent data from intracardiac recordings, many of these correlations have been shown to be incorrect and thus the use of the eponyms adds confusion to discussions about them. For instance, the pathways described by Kent (AV nodal–like tissue at the free-wall AV valve annulus) more resemble atriofascicular fibers than they do typical AV fibers, and atriofascicular fibers in turn possess the physiology initially (incorrectly) attributed to Mahaim fibers. Table 18.1 displays some of the terminology; it is evident why use of eponymous terms is discouraged.

PATHOPHYSIOLOGY

Wolff-Parkinson-White Syndrome

WPW *pattern* refers to the constellation of ECG abnormalities related to the presence of a manifest AV BT (i.e., ventricular preexcitation: short PR interval, delta wave, wide QRS complex) in asymptomatic patients (Fig. 18.1). WPW *syndrome* refers to the combination of ventricular preexcitation and either a documented tachyarrhythmia or symptoms of a tachyarrhythmia.¹

Because the AV BT typically conducts faster than the AVN, the onset of ventricular activation is earlier than if depolarization occurred only via the AVN, resulting in a shortened PR (P-delta) interval. Furthermore, because the BT exhibits practically nondecremental conduction, the early ventricular activation (i.e., P-delta interval) remains almost constant at all atrial rates (Fig. 18.2).

Preexcited intraventricular conduction in WPW propagates from the insertion point of the AV BT in the ventricular myocardium via direct muscle-to-muscle conduction. This process is inherently slower than ventricular depolarization resulting from rapid HPS conduction. Thus, although the initial excitation of the ventricles (via the BT) occurs earlier, it is followed by slower activation of the ventricular myocardium than occurs normally. The net effect is that the QRS complex consists of fusion between the early ventricular activation caused by preexcitation with the later ventricular activation resulting from impulse propagation through the AVN-HPS to the ventricles. The initial part of ventricular activation resulting in the upstroke of the QRS complex is slurred because of slow muscle-to-muscle conduction; this is termed a *delta wave*.

Depending on the relative contribution from ventricular activation by the normal AVN-HPS versus the manifest BT, a variable degree of preexcitation occurs. The more rapid the conduction along the BT in relation to the AVN, the greater the amount of myocardium depolarized

TABLE 18.1 Historical Description of Different Bypass Tracts

Eponymous Pathway	Anatomical Description	Proposed Physiological Role/Syndrome	Actual Physiologic Role
Kent bundle	Clusters of nodal cells at nonseptal AV junction	Anomalous AV connection/WPW syndrome	None (possibly atriofascicular pathways)
James fiber	Atriocompact nodal connection	LGL syndrome	Enhanced AVN conduction
Brechenmacher fiber	Atrio-Hisian connection	LGL syndrome	Enhanced AVN conduction
Mahaim fiber	Connection from compact AVN to ventricle	Septal WPW pathways with decremental conduction	Probably none
Paladino fiber	Connection from proximal AVN to ventricle	Septal WPW pathways with decremental conduction	Probably none

AV, Atrioventricular; AVN, atrioventricular nodal; LGL, Lown-Ganong-Levine; WPW, Wolff-Parkinson-White.

Fig. 18.1 Ventricular Preexcitation. Three surface electrocardiogram leads during normal sinus rhythm. The first sinus P wave is conducted over the normal atrioventricular node-His Purkinje system (AVN-HPS), resulting in a normal PR interval (PRI) and a normal QRS complex. The second P wave is conducted over the AVN and a bypass tract (BT). AV conduction over the BT is faster than over the AVN, resulting in pre-excitation of the ventricle and shortening of the PRI. Then, preexcited intraventricular conduction propagates from the insertion point of the BT in the ventricular myocardium via direct muscle-to-muscle (slow) conduction, producing an initial slurred “delta” wave (shaded area of the QRS complex). The rest of the QRS complex is produced by the rapidly conducting HPS. Therefore the preexcited QRS results from fusion between activation over the BT (which accounts for the initial delta wave) and activation over the AVN-HPS (which accounts for the rest of the QRS complex).

via the BT, resulting in a more prominent or wider delta wave and increasing prolongation of the QRS complex duration.¹

Atrioventricular Bypass Tracts

The cardiac skeleton consists of four rings of dense connective tissue that surround the AV canals (mitral and tricuspid) and extend to the origins of the aorta and the pulmonary trunk, providing structure and support for the heart as well as electrical isolation between the atria and the ventricles. The aortic valve occupies the central position with the other valve rings attached to it. The right fibrous trigone includes the triangular formation between the aortic valve and the medial parts of the tricuspid and mitral valves, and it represents the largest thickening and strongest portion of the cardiac skeleton. Together with the membranous septum, the right fibrous trigone constitutes the central fibrous body (see Fig. 9.1).

The AV junctions are the areas of the heart where the atrial musculature connects to the annuli of the mitral and tricuspid valves. The AVN-HPS, which lies in the septal component of the AV junction, is the only normal electrical connection between the atria and the ventricles. The fibrous skeleton and AV valvular annuli (annulus fibrosus) act as insulators to prevent electrical impulses from conducting to the ventricles by any other route. The main function of the AVN is modulation of atrial impulse transmission to the ventricles, thereby coordinating atrial and ventricular contractions; it receives, delays, and conveys atrial impulses to the ventricles.

AV BTs are aberrant muscle bundles that connect the atria to the ventricles outside of the normal AV conduction system. AV BTs are found most often in the parietal AV junctional areas, including the paraseptal areas. They breach the insulation provided by the fibrofatty tissues of the AV groove (sulcus tissue) and the hinge lines (fibrous annulus) of the valves. They are rarely found in the area of fibrous continuity between the aortic and mitral valves because in this area there is usually a wide gap between the atrial myocardium and ventricular myocardium to accommodate the aortic outflow tract. The remainder of the AV groove may be divided into quadrants consisting of the left free wall, right free wall, and posteroseptal and anteroseptal spaces. The distribution of BTs within these regions is not homogeneous—46% to 60% of BTs are found within the left free-wall space; 25% are within the posteroseptal space; 13% to 21% of BTs are within the right free-wall space; up to 7% are within the right superoparaseptal (formerly called anteroseptal) space; and less than 5% are located in the midseptum (Fig. 18.3).

AV BTs are usually short and very thin muscular strands (typically 5 to 10 mm in length, with a maximal diameter of 0.1 to 7 mm) but can occasionally exist as broad bands of tissue. They can course through the AV groove at variable depths ranging from subepicardial to subendocardial locations. The AV BT can run in an oblique course rather than perpendicular to the transverse plane of the AV groove. As a result, the fibers can have an atrial insertion point that is transversely from less than one to several centimeters removed from the point of ventricular attachment. Some posteroseptal pathways insert into coronary sinus (CS) musculature rather than atrial myocardium and can be associated with the coronary venous system or diverticula from a CS branch vein.

Multiple AV BTs occur in 5% to 10% of patients. BTs are defined as multiple when they are separated by more than 1 to 3 cm at the AV junction. The most common combination of widely spaced multiple BTs is posteroseptal and right free-wall BTs. The incidence of multiple BTs is particularly high in patients with antidromic atrioventricular reentrant tachycardia (AVRT) (50% to 75%), patients in whom atrial fibrillation (AF) resulted in ventricular fibrillation (VF), and patients with Ebstein anomaly.

Although the majority (approximately 60%) of AV BTs conduct both anterogradely and retrogradely (i.e., bidirectionally), some AV BTs are capable of propagating impulses in only one direction. BTs that conduct only in the anterograde direction are uncommon (less than 5%), often cross the right AV groove, and frequently possess decremental conduction properties. On the other hand, BTs that conduct only in the retrograde direction occur more frequently, accounting for 17% to 37% of all BTs. When the BT is capable of anterograde conduction, ventricular preexcitation is usually evident during normal sinus rhythm (NSR), and the BT is referred to as *manifest*. BTs capable of retrograde-only conduction are referred to as *concealed*.

Because working myocardial cells make up the vast majority of AV BTs, conduction over those BTs is mediated by the rapid inward sodium current, similar to normal His-Purkinje tissue and atrial and ventricular myocardium. Therefore AV BTs have rather constant anterograde and retrograde conduction at all rates until the refractory period is reached, at which time conduction is completely blocked. Thus conduction over AV BTs usually behaves in an all-or-none fashion (i.e., nondecremental conduction), although with careful measurement, there is often a small amount of prolongation of conduction intervals (10 to 15 milliseconds) over the BT when the pacing rate is just below that at which block occurs. In contrast, the AVN, which depends on the slow inward calcium current for generation and propagation of its action potential, exhibits what has been called *decremental conduction*, whereby conduction time of the impulse propagating through the AVN prolongs as the atrial

Fig. 18.2 Wolf-Parkinson-White Electrocardiogram (ECG) Pattern. Surface ECG of normal sinus rhythm with ventricular preexcitation (*left*) and without preexcitation (*right*) in the same patient.

Fig. 18.3 Locations of Atrioventricular (AV) Bypass Tracts by Anatomical Region. Tricuspid and mitral valve annuli are depicted in a left anterior oblique view. Locations of the coronary sinus, AV node, and His bundle are shown. AV bypass tracts may connect atrial to ventricular myocardium in any of the regions shown. (From Miller JM, Zipes DP. Therapy for cardiac arrhythmias. In: Libby P, Bonow R, Mann DL, et al., eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 8th ed. Philadelphia: WB Saunders; 2007:779–830.)

cycle length (CL) shortens. Thus AV conduction is more rapid through the AV BT than through the AVN, a difference that is exaggerated at faster heart rates. This difference has potentially great clinical importance. A primary function of the AVN is to limit the number of impulses conducted from the atria to the ventricles, which is particularly important during fast atrial rates (e.g., AF or atrial flutter [AFL]) when only a fraction of impulses are conducted to the ventricles, whereas the remainder are blocked in the AVN. However, in the presence of nondecrementally conducting AV BTs with short refractory periods, these arrhythmias can lead to very fast ventricular rates that can degenerate into VF.

Atrioventricular Reentry

AVRT is a macroreentrant tachycardia with an anatomically defined circuit that consists of two distinct pathways, the normal AV conduction system and an AV BT, linked by common proximal (atrial) and distal (ventricular) tissues. If sufficient differences in conduction time and refractoriness exist between the normal conduction system and the BT, a properly timed premature impulse of atrial or ventricular origin can initiate reentry. AVRTs are the most common (80%) tachycardias associated with the WPW syndrome. AVRT is divided into orthodromic and antidromic according to the direction of conduction in the AVN-HPS (Fig. 18.4). Orthodromic indicates normal direction (anterograde) of conduction over AVN-HPS during AVRT.

Fig. 18.4 Bypass Tract–Related Tachycardias. Schematic representation of the reentrant circuit during orthodromic atrioventricular reentrant tachycardia (AVRT), antidromic AVRT, preexcited atrial tachycardia (AT), and preexcited atrioventricular nodal reentrant tachycardia (AVNRT) using a left-sided bypass tract (BT). HB, His bundle; LB, left bundle branch; RB, right bundle branch.

Orthodromic Atrioventricular Reentrant Tachycardia

In orthodromic AVRT, the AVN-HPS serves as the anterograde limb of the reentrant circuit (i.e., the pathway that conducts the impulse from the atria to the ventricles), whereas an AV BT serves as the retrograde limb (see Figs. 18.4 and 18.5). Approximately 50% of BTs participating in orthodromic AVRT are manifest (able to conduct bidirectionally) and 50% are concealed (able to conduct retrogradely only). Therefore a WPW pattern may or may not be present on the surface ECG during NSR. When preexcitation is present, the delta wave seen during NSR is lost during orthodromic AVRT because anterograde conduction during the tachycardia occurs over the normal AV conduction system, and not via the BT (i.e., the ventricle is not preexcited). Orthodromic AVRT accounts for approximately 90% to 95% of AVRT episodes in patients with a manifest BT and 35% of all paroxysmal supraventricular tachycardias (SVTs).¹

Antidromic Atrioventricular Reentrant Tachycardia

Antidromic AVRT is a preexcited AVRT whereby an AV BT serves as the anterograde limb and the AVN-HPS serves as the retrograde limb of the reentrant circuit (see Figs. 18.4 and 18.5). Consequently, the QRS complex during antidromic AVRT is fully preexcited (i.e., the ventricles are activated totally by the BT with no contribution from the normal conduction system). The BT involved in the antidromic AVRT circuit must be capable of anterograde conduction and, therefore, preexcitation is typically observed during NSR. Other, less frequent, forms of preexcited AVRT utilize one AV BT as the anterograde conduction and a second BT for retrograde conduction or a combination of one BT plus the AVN-HPS in either direction (eFig. 18.1).¹

Clinically, antidromic AVRT is much less frequent than orthodromic AVRT, occurring in less than 5% of patients with WPW syndrome, and can be induced in the electrophysiology (EP) laboratory in less than 10%. The low prevalence of antidromic AVRT is related to the EP properties of the AVN, because good retrograde ventriculoatrial (VA)

conduction is required to sustain tachycardia. Clinical presentation, sex, age, and orthodromic AVRT induction appear similar in patients with and without inducible antidromic AVRT. Patients with antidromic AVRT induction more frequently have BTs with more rapid conduction properties than other WPW patients.²

Susceptibility to antidromic AVRT appears to be facilitated by a distance of at least 4 cm between the BT and the normal AV conduction system. Consequently, most antidromic AVRTs use a lateral (right or left) BT as the anterograde route for conduction. Because posteroseptal BTs are in close proximity to the AVN, those BTs are rarely part of antidromic AVRT if the other limb is the AVN and not a second free-wall BT. Up to 50% to 75% of patients with spontaneous antidromic AVRT have multiple BTs (manifest or concealed), which may or may not be utilized as the retrograde limb during the tachycardia.²

Permanent Junctional Reciprocating Tachycardia

Permanent junctional reciprocating tachycardia (PJRT) is a rare form of nearly incessant orthodromic AVRT mediated by a concealed, retrogradely conducting AV BT that has slow and decremental conduction properties. Conduction properties of this retrograde BT are slower than the anterograde conduction properties of the AVN and those of typical fast BTs found in patients with AVRT. The BT in PJRT is most often located in the posteroseptal region, although other portions of the AV groove can also harbor this unusual pathway. Because these BTs are almost always concealed and have slow conduction, all elements necessary for reentry are present at all times, and thus PJRT can be present much of the time (i.e., incessant), with only short interludes of sinus rhythm. The incessant nature of PJRT can result in tachycardia-induced cardiomyopathy.^{1,3}

Other Arrhythmias Associated With Wolff-Parkinson-White Syndrome

Atrial tachycardia (AT), AFL, AF, and atrioventricular nodal reentrant tachycardia (AVNRT) can all coexist with a BT. In these preexcited tachycardias, the BT serves as a bystander route for ventricular or atrial activation, and is not required for the initiation or maintenance of the arrhythmia.

Atrioventricular Nodal Reentrant Tachycardia and Atrial Tachycardia

Both AVNRT and AT can use the bystander BT to transmit impulses to the ventricle (see Fig. 18.4). When AVNRT occurs in the WPW syndrome, the arrhythmia can be difficult to distinguish from AVRT without EP testing.

Atrial Fibrillation

The overall incidence of AF in patients with WPW syndrome varies from 12% to 39%. AF is typically paroxysmal. Persistent AF is rare in these patients. AF is most common in patients with anterogradely conducting BTs. Patients with antidromic AVRT, multiple BTs, and BTs that have a short anterograde effective refractory period (ERP) are more prone to develop AF. In individuals with WPW, AF is often preceded by AVRT that degenerates into AF (Fig. 18.6).

The frequency with which intermittent AF occurs in patients with the WPW syndrome is striking because of the low prevalence of coexisting structural heart disease or other predisposing factors for AF. This observation suggests that the AV BT itself can be related to the genesis of AF, supported by the fact that when the BT is ablated, AF may not recur.

The mechanisms by which AVRT precipitates AF are not well understood. The rapid atrial rate can cause disruption in atrial activation and reactivation, creating an EP substrate conducive to AF. The observation

eFig. 18.1 Preexcited Atrioventricular Reentrant Tachycardia. The anterograde limb of the reentry circuit is mediated by a right lateral bypass tract (BT), as indicated by the preexcited QRS morphology. The retrograde limb of the circuit is mediated by a left lateral BT, as indicated by the eccentric atrial activation sequence. NSR

Antidromic AVRT

Orthodromic AVRT

Fig. 18.5 Orthodromic and Antidromic Atrioventricular Reentrant Tachycardias (AVRTs) in a Patient With a Bidirectional Left Posteroseptal Bypass Tract (BT). Ventricular preexcitation is evident during normal sinus rhythm (NSR). The narrow complex tachycardia represents orthodromic AVRT using the BT as the retrograde limb of the reentrant circuit. Antidromic AVRT utilizes the BT for anterograde atrioventricular conduction, resulting in wide complex tachycardia.

that most patients with BT and AF who undergo BT ablation are cured of both AVRT and AF is compatible with this hypothesis. Another possibility is that the complex geometry of networks of BTs predisposes to AF by fractionation of the activation wavefronts. Localized reentry has been recorded in some patients, using direct recordings of the activation of the BTs. Hemodynamic changes, atrial stretch caused by atrial contraction against closed AV valves during ventricular systole, can also play a role. Ablation of the BT can cure AF in more than 90% of

patients; however, vulnerability to AF persists in up to 56%, and the response to atrial extrastimulation (AES) is also unaltered by ablation.

AF in younger WPW patients is usually associated with the BT and is unlikely to occur after ablation; in contrast, older patients may have recurrence of AF from causes unrelated to the BT. Nonetheless, recent studies have challenged the role of BT ablation in modulating the risk of AF particularly in adult patients, and show persistently higher rates of AF in WPW patients (hazard ratio, 4.77) compared with the general

Fig. 18.6 Antidromic Atrioventricular Reentrant Tachycardia (AVRT) Converting Into Nonsustained Preexcited Atrial Fibrillation (AF). Normal sinus rhythm (NSR) follows. Preexcitation is mediated via a left anterior bypass tract.

population despite catheter ablation of the BT.⁴ Trends of increased risk of AF in ablated WPW patients suggest that mechanisms other than those directly related to the presence of a BT, such as underlying atrial myopathy, may play a role in AF genesis.

Atrial Flutter

About 4% of WPW patients present with AFL. AFL is the most common (60%) regular preexcited tachycardia in patients with WPW syndrome. AFL is caused by a macroreentrant circuit within the RA and therefore exists independently of the BT, and AFL does not have the same causal association to AV BTs as AF. In some patients with WPW syndrome who develop AFL, AVRT is often the initiating event. This relationship can be mediated by contraction-excitation feedback into the atria during the AVRT.

AFL, like AF, can conduct anterogradely via a BT causing a preexcited tachycardia. Depending on the various refractory periods of the normal and pathological AV conduction pathways, AFL can potentially conduct 1:1 to the ventricles during a preexcited tachycardia, making the arrhythmia difficult to distinguish from VT (see Fig. 12.10).

Ventricular Fibrillation and Sudden Cardiac Death

The mechanism of sudden cardiac death (SCD) in patients with WPW is likely the occurrence of AF or AFL with a very rapid ventricular rate, which provokes VF. Although the frequency with which AF with rapid AV conduction via a BT degenerates into VF is unknown, the incidence of SCD in patients with WPW syndrome is rather low, ranging from 0% to 0.39% annually in several large case series. The trigger for AF in this population of patients is generally an episode of AVRT. In fact, most patients who have been resuscitated from VF secondary to pre-excitation have a previous history of AVRT, AF, or both. Nonetheless, SCD can be the first manifestation of WPW syndrome.⁵

Several factors can help identify the patient with WPW who is at increased risk for VF, including symptomatic AVRT, septal location of the BT, presence of multiple BTs, and male gender. In addition, the risk of SCD associated with WPW appears highest in the first two decades of life.¹ Nonetheless, it is clear that the most important factor for the occurrence of VF in these patients is the ability of the BT to conduct rapidly to the ventricles. This is best measured by determining the shortest and average preexcited R-R intervals during AF or, alternatively,

by measuring the anterograde ERP of the BT. If the BT has a very short anterograde ERP (less than 250 milliseconds), a rapid ventricular response can occur with degeneration of the rhythm to VF. A short preexcited R-R interval during AF (≤ 220 milliseconds) appears to be a sensitive clinical marker for identifying children at risk for SCD, although its positive predictive value in adults is only 19% to 38%.⁵

Drug therapy can be an additional determinant of the risk of VF in patients with preexcitation. Several pharmacological agents can potentially enhance BT conduction and increase the ventricular rate during AF and, hence, increase the risk of VF (see later).

Ventricular Tachycardia

Coexisting VT is uncommon in patients with WPW syndrome because structural heart disease is very infrequent in this young patient population. Naturally, older patients are subject to coronary artery and other diseases that can cause VT.

EPIDEMIOLOGY AND NATURAL HISTORY

Wolff-Parkinson-White Pattern

The prevalence of WPW pattern on the surface ECG is 0.1% to 0.3% in the general population.¹ The prevalence is increased to 0.55% among first-degree relatives of affected patients, suggesting a familial component. The annual incidence of newly diagnosed cases of preexcitation in the general population was substantially lower (0.004%) in a diverse population of residents from Olmsted County, Minnesota, 50% of whom were asymptomatic. The incidence in men is twice that in women, and is highest in the first year of life, with a secondary peak in young adulthood.⁵

The WPW pattern on the surface ECG can be intermittent and can even permanently disappear with loss of anterograde but preserved retrograde conduction. Loss of preexcitation has been observed in up to 31% of adults and in 0% to 33% of children and adolescents over a 5-year time period. Intermittent and persistent loss of preexcitation may indicate that the BT has a relatively longer baseline ERP, which makes it more susceptible to age-related degenerative changes and variations in autonomic tone.⁶

Wolff-Parkinson-White Syndrome

The prevalence of the WPW syndrome is substantially lower than that of the WPW ECG pattern. At present, it is estimated that approximately 65% of adolescents and 40% of adults over 30 years of age with a WPW pattern on a resting ECG are asymptomatic.⁵

The occurrence of arrhythmias is related to the age at the time preexcitation is discovered and can vary with location and EP properties of the BT. AVRT manifests early in life, with an average of more than 10 years separating the time of clinical presentation of AVRT versus that of AVNRT.¹ Up to 70% of children (8 to 12 years of age) who are asymptomatic at the time of diagnosis of WPW ECG pattern remain asymptomatic over median follow-up of 57 months. About 30% eventually develop an arrhythmic event, which can be potentially life-threatening in approximately 10% of patients. In contrast, only a minority (10%) of adults who are asymptomatic at the time of diagnosis of ventricular preexcitation develop cardiac arrhythmias over median follow-up of 67 months, which can be potentially life-threatening in approximately 5% of patients. The vast majority of patients in whom preexcitation is first uncovered after the age of 40 remain asymptomatic.⁵ In a large meta-analysis, the annual risk of developing SVT was 0.25% of WPW patients.⁷

A male predominance among WPW patients has been observed. Furthermore, men tend to have a higher incidence of antidromic AVRT, more prevalent left-sided BTs, and shorter anterograde BT ERP. Also,

men usually present with AVRT at an older age than women. In contrast, women were found to have a higher prevalence of multiple BTs, orthodromic AVRT, and right-sided BTs. In addition, Asians appear to have right free-wall BTs substantially more frequently than other races.^{8,9}

Sudden Death

The incidence of SCD among patients with asymptomatic preexcitation is difficult to ascertain. A large meta-analysis (including 1869 patients with asymptomatic ventricular preexcitation from 20 studies with 11,722 patient-years of follow-up) found a total of 10 cases of SCD, with SCD rates between 0 and 4.5 events per 1000 person-years of follow-up, and an overall risk of SCD in adults and children of 2.5 per 1000 person-years (or 3% to 4% over a lifetime). Italian studies reported all but one SCD event.^{6,7}

In general, children seem to have a numerically higher event rate than adults. The majority of victims were between the ages of 10 and 40 years. Patients with WPW who are most susceptible to SCD are symptomatic; however, SCD can be the first event in patients with asymptomatic preexcitation.⁷ Several characteristics have been reported among patients who experienced potentially life-threatening events, including younger age (less than 30 years), male gender, history of AF, prior syncope, associated congenital or other heart disease, and familial WPW. Low-risk WPW patients also showed a characteristic EP profile (older age, lower tachyarrhythmia inducibility, longer anterograde refractory ERP of BTs, and low likelihood of baseline retrograde BT conduction or multiple BTs).⁷

Associated Cardiac Abnormalities

Most patients with AV BTs do not have coexisting structural cardiac abnormalities, except for those that are age related. The association of ventricular preexcitation with structural congenital heart defects is well recognized. Up to 20% of children with WPW also have congenital heart disease. Associated congenital abnormalities, when present, are more likely to be right sided than left sided. Ebstein anomaly is the congenital lesion most strongly associated with the WPW syndrome. As many as 10% of such patients have one or more BTs; most of these are located in the right free-wall or the right posteroseptal space. Ventricular preexcitation has also been described in patients with transposition of great arteries, pulmonary atresia, patent ductus arteriosus, tetralogy of Fallot, total anomalous pulmonary venous return, and ventricular septal defects.^{5,6}

Familial Wolff-Parkinson-White Syndrome

Typically, WPW syndrome occurs sporadically; however, in a minority of cases it is inherited. A familial form of WPW has infrequently been reported and is usually inherited as an autosomal dominant trait. Among patients with the WPW syndrome, 3.4% have first-degree relatives with a preexcitation syndrome. The genetic cause of a rare form of familial WPW syndrome has been described. The clinical phenotype is characterized by the presence of preexcitation on the ECG, frequent SVTs (including AF), progressive conduction system disease, and left ventricular (LV) hypertrophy (distinct from sarcomeric hypertrophic cardiomyopathy). Patients typically present in late adolescence or the third decade with syncope or palpitations. Premature SCD occurred in 10% of patients. Paradoxically, by the fourth decade of life, progression to advanced SND or AV block (with the loss of preexcitation) requiring pacemaker implantation was common. Approximately 80% of the patients older than 50 years had chronic AF. Causative mutations in the *PRKAG2* gene were identified in these families. The *PRKAG2* gene encodes the gamma-2 regulatory subunit of the adenosine monophosphate (AMP)-activated protein kinase, which is a key regulator of metabolic pathways, including glucose metabolism. The penetrance

of the disease for WPW syndrome was complete, but the expression was variable. The described phenotype of this syndrome is similar to the autosomal recessive glycogen storage disease, Pompe disease. Given the function of the AMP-activated protein kinase and this similarity, the PRKAG2 syndrome is likely a cardiac-specific glycogenosis syndrome. This syndrome thus belongs to the group of genetic metabolic cardiomyopathies, rather than to the congenital primary arrhythmia syndromes. The annulus fibrosus, which normally insulates the ventricles from the atria, is thinned and disrupted by glycogen-filled myocytes, and these anomalous microscopic AV connections, rather than morphologically distinct BTs, appear to provide the anatomic substrate for ventricular preexcitation. Of note, certain mutations in PRKAG2 have been associated with nodoventricular BTs.¹⁰

Another genetic form of WPW syndrome is associated with mutations in the bone morphogenetic protein-2 (BMP2) gene, which belongs to the class of transforming growth factor, The TGF- β -superfamily of proteins, and is involved in the development of the annulus fibrosus. This syndrome is characterized by variable cognitive deficits and dysmorphic features in addition to ventricular preexcitation.¹¹

Concealed Bypass Tracts

The true prevalence of concealed BTs is unknown because, unlike the situation with the WPW ECG pattern, these BTs are concealed on the surface ECG and are only expressed during AVRT; only symptomatic patients undergo EP testing. As noted, orthodromic AVRT accounts for approximately 95% of AVRTs and 35% of all paroxysmal SVTs, and 50% of the BTs that participate in orthodromic AVRT are concealed. SVTs using a concealed BT have no gender predilection and tend to occur more frequently in younger patients than in those with AVNRT; however, significant overlap exists. PJRT most often occurs in early childhood, although clinically asymptomatic patients presenting later in life are not uncommon.

CLINICAL PRESENTATION

The majority of patients with preexcitation are asymptomatic and are discovered incidentally on an ECG obtained for unrelated reasons. When symptomatic arrhythmias occur in the WPW patient, the disorder is called the WPW syndrome. The two most common types of arrhythmias in the WPW syndrome are AVRT and AF. Patients with AVRT experience symptoms characteristic of paroxysmal SVT with abrupt onset and termination, including rapid and regular palpitations, chest pain, dyspnea, presyncope, and rarely, syncope. Episodes can last from seconds to several hours. Symptoms are usually mild and short-lived and terminate spontaneously or with vagal maneuvers. However, occasionally patients present with disabling symptoms, especially in the presence of structural heart disease.^{1,12}

AVRT, which in general is well tolerated by the patient when additional heart disease is absent, can deteriorate into AF; the latter can be a life-threatening arrhythmia if the BT has a short anterograde refractory period, resulting in very fast ventricular rates, with possible degeneration into VF and SCD. The incidence of SCD in patients with the WPW syndrome has been estimated to range from 0.15% to 0.39% over a 3- to 10-year follow-up. It is unusual for cardiac arrest to be the first symptomatic manifestation of WPW syndrome. Conversely, in about 50% of cardiac arrest cases in WPW patients, it is the first manifestation of WPW syndrome.

PJRT commonly presents as a frequently recurring or incessant tachycardia that is refractory to drug therapy and can lead to tachycardia-induced cardiomyopathy and heart failure symptoms.

Rarely, significant ventricular preexcitation during NSR can result in ventricular dysfunction secondary to dyssynchronous ventricular

contraction. Improvement of left ventricular ejection fraction has been described after ablation of septal BTs in pediatric patients.⁵

INITIAL EVALUATION

History, physical examination, and 12-lead ECG constitute an appropriate initial evaluation. In patients with brief, self-terminating episodes of palpitations, an event recorder is the most effective way to obtain ECG documentation. Also, echocardiographic examination is recommended to exclude structural heart disease.

Several other noninvasive tests have been proposed as useful for evaluating symptomatic patients and risk-stratifying patients for SCD risk. However, the sensitivity and specificity of noninvasive testing have been shown to be limited. Invasive EP testing may be considered in patients with arrhythmias and those with a WPW ECG pattern when noninvasive testing does not lead to the conclusion that the anterograde ERP of the BT is relatively long. However, a strategy to perform an EP study for all asymptomatic patients with the WPW ECG pattern for the purpose of risk stratification is still controversial and not widely accepted.

Methods for Evaluation of Bypass Tract Refractory Period

Demonstration of Intermittent Preexcitation

Intermittent preexcitation has historically been thought to confer a lower risk of SCD than persistent preexcitation. Observation of intermittent loss of the preexcitation pattern on ambulatory monitoring or serial ECGs is generally correlated with a long BT anterograde ERP. The longer refractory period of the BT decreases the frequency of manifest preexcitation during NSR and is expected to lower the risk of mediating rapid preexcited ventricular activation during AF. Nevertheless, EP studies in symptomatic patients with intermittent preexcitation found that 10% to 24% can have BTs capable of conducting at rapid rates during AF (with anterograde ERP or shortest preexcited R-R interval less than 250 milliseconds), perhaps related to autonomic influences. However, similar findings have not yet been demonstrated in asymptomatic patients with intermittent preexcitation.^{13,14}

Intermittent preexcitation can be observed on ambulatory monitoring in up to 67% of patients. It is important, however, to distinguish intermittent preexcitation from inapparent preexcitation (see later) and from a bigeminal ventricular rhythm with a long coupling interval.^{1,5} Although intermittent preexcitation is a predictor of poor anterograde conduction through the BT, it has rarely been observed in some patients with cardiac arrest. Furthermore, the presence of intermittent preexcitation does not predict retrograde conduction properties of the BT nor preclude the development of AVRT.⁵

Loss of Preexcitation During Exercise

Demonstration of a sudden loss of preexcitation (indicated by abrupt loss of the delta wave associated with prolongation of the PR interval and normalization of the QRS) during exercise is consistent with block in the BT and is consistent with a long BT ERP (greater than 300 milliseconds). Importantly, rapid AVN conduction during exercise can potentially mask persistent preexcitation. Therefore only *abrupt* and *complete* loss of preexcitation during exercise should be sought as a surrogate of a long anterograde ERP of the BT.⁵

Loss of preexcitation during exercise is a good predictor that the patient is not at risk for VF even during sympathetic stimulation. However, the frequency of block in the BT during exercise is low (approximately 10% to 20%), and thus sensitivity of this test is poor. On the other hand, persistence of preexcitation during exercise stress has a sensitivity of 96% but a specificity of only 17% in predicting either a

shortest preexcited R-R less than 250 milliseconds during AF or a BT ERP of less than 250 milliseconds (positive predictive value of 40% and negative predictive value of 88%).⁵

Bypass Tract Conduction Block in Response to Antiarrhythmic Agents

When the administration of ajmaline (1 mg/kg IV over 3 minutes) or procainamide (10 mg/kg IV over 5 minutes) results in complete block of the BT during NSR, a long anterograde ERP (greater than 270 milliseconds) of the BT is likely. The shorter the BT ERP, the less likely it would be blocked by these drugs. Also, the amount of ajmaline required to block conduction over the BT correlates with the duration of the anterograde ERP of the BT. However, the incidence of BT block in response to these drugs is low and, although the occurrence of block predicts a long ERP of the BT, failure to produce block does not necessarily suggest a short ERP. Moreover, pharmacological testing is carried out at rest and therefore does not indicate what effect the drug will have on the BT ERP during sympathetic stimulation, such as exercise, emotion, anxiety, and recreational drug use. Importantly, the specificity of loss of preexcitation after administration of sodium blockers is poor compared to the shortest preexcited R-R intervals during inducible AF. Given these limitations, pharmacologic challenge is no longer routinely utilized.⁵

Evaluation of Ventricular Response During Atrial Fibrillation

During spontaneous or induced AF, the propensity for rapid AV conduction can be judged by the interval between consecutively preexcited QRS complexes. A mean preexcited R-R interval greater than 250 milliseconds and a shortest preexcited R-R greater than 220 milliseconds predict low risk for SCD, with a negative predictive value of more than 95%; however, the positive predictive value is low (20%).⁵

Response of Preexcitation to Transesophageal Atrial Stimulation

There is good correlation between the value of the anterograde ERP of the BT obtained during single-test programmed atrial stimulation and atrial pacing at increasing rates and the ventricular rate during AF. Programmed electrical stimulation of the atrium can be performed by the transesophageal route and the value of the anterograde ERP of the BT can be determined.

Electrophysiological Testing

Programmed atrial stimulation is used to evaluate the anterograde ERP of the BT. Because BT refractoriness shortens with decreasing pacing cycle length (PCL), the ERP should be determined at multiple PCLs (preferably ≤ 400 milliseconds). In addition, atrial stimulation should be performed close to the BT atrial insertion site to obviate the effect of intraatrial conduction delay. Incremental-rate atrial pacing is performed to determine the maximal rate at which 1:1 conduction over the BT occurs. Induction of AF should be performed to determine the average and the shortest R-R interval during preexcited AF. Atrial and ventricular stimulation is also performed to evaluate inducibility of AVRT as well as the number and location of BTs.⁵

A shortest preexcited R-R interval less than 220 to 250 milliseconds during AF has been shown to be the best discriminator of those at risk of VF, with a high sensitivity (88% to 100%) and a high negative predictive value for identifying children and young adults with WPW syndrome at risk for VF. However, the positive predictive value is low (19% to 38%), largely due to the very low incidence of SCD in these patients. Also, a shortest preexcited R-R interval less than 250 milliseconds during AF has been noted in 20% to 26% of asymptomatic adults with a WPW pattern, and in up to 67% when isoproterenol is

administered. Thus, although isoproterenol raises the sensitivity of invasive EP testing, it markedly reduces the specificity.⁵

On the other hand, BT ERP less than 240 milliseconds appears to significantly correlate with only AVRT inducibility, but as an isolated variable, it is less predictive of life-threatening events and exhibits significant overlap between WPW patients with VF and those without VF. The presence of multiple BTs and the ability to induce sustained AVRT, especially when AVRT spontaneously degenerates into AF, have been proposed to predict risk of malignant ventricular arrhythmias. The lack of retrograde conduction over the BT appears to be at lower risk for SCD. However, the predictive value of these criteria remains limited and significant overlap exists.^{1,5}

PRINCIPLES OF MANAGEMENT

Acute Management

Symptomatic Patients With Concealed Bypass Tracts

Patients with orthodromic AVRT utilizing a concealed BT are treated in a similar fashion as those with paroxysmal SVT. Vagal maneuvers (including Valsalva and carotid sinus massage) are the first-line intervention for acute conversion of the tachycardia; though the overall success rate is limited (approximately 28%). If SVT persists, adenosine is recommended, and it offers a success rate of 90% to 95%. For refractory tachycardia, IV diltiazem, verapamil, or beta-blockers can terminate orthodromic AVRT in the majority of patients. Synchronized cardioversion is recommended for hemodynamically unstable patients and for those refractory or intolerant to drug therapy (Fig. 18.7).¹

Symptomatic Patients With Manifest Bypass Tracts

In patients with manifest preexcitation during NSR presenting with AVRT (orthodromic or antidromic), vagal maneuvers are the first-line intervention for tachycardia termination (see Fig. 18.7). For persistent SVT, adenosine is recommended. Importantly, adenosine should be used with caution because it can induce AF with a rapid ventricular rate in the presence of an anterogradely conducting BT. This is unusual and should not be viewed as a contraindication to adenosine use, but one should be prepared for emergency cardioversion before administering adenosine to SVT patients.¹

For refractory AVRT, IV diltiazem, verapamil, or beta-blockers can be considered to block conduction in the AVN, which represents either the retrograde or anterograde limb in the AVRT circuit. AVN blocking drugs, however, are ineffective in patients with preexcited AVRT that utilizes two separate BTs for anterograde and retrograde conduction. Drug treatment directed at the BT (ibutilide, procainamide, flecainide) may also be considered. When drug therapy fails or hemodynamic instability is present, electrical cardioversion should be considered. It is important to note that IV diltiazem and verapamil can result in hemodynamic collapse if the AVRT does not terminate or AF is induced with rapid conduction over the BT degenerating to VF, and one must be prepared for immediate electrical cardioversion if that occurs (see later).

Preexcited Atrial Fibrillation

In patients with AF or AFL, ventricular preexcitation, and rapid ventricular response, prompt direct-current cardioversion is recommended, especially when hemodynamic compromise is present. IV procainamide or ibutilide to restore NSR or slow the ventricular rate may be considered in hemodynamically stable patients. Both drugs slow BT conduction.

Importantly, drugs that preferentially slow AVN conduction without prolonging BT refractoriness (such as verapamil, diltiazem, beta-blockers, adenosine, oral or IV digoxin, and IV amiodarone) can accelerate the ventricular rate and potentially precipitate hemodynamic collapse and

Fig. 18.7 Acute Treatment of Orthodromic Atrioventricular Reentrant Tachycardia (AVRT). ^aFor rhythms that break or recur spontaneously, synchronized cardioversion is not appropriate. IV, Intravenous. (From Page RL, Joglar JA, Caldwell MA, et al. 2015 ACC/AHA/HRS guideline for the management of adult patients with supraventricular tachycardia: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines and the Heart Rhythm Society. *J Am Coll Cardiol*. 2016;67:e27–e115.)

VF in high-risk patients. Several mechanisms are probably involved; hypotension produced by some of those medications is followed by a sympathetic discharge that enhances BT conduction. Furthermore, slowing or blocking conduction through the AVN prevents competitive concealed retrograde conduction into the BT by normally conducted beats and, as a result, can potentially enhance conduction over the BT. In addition, the rapid and irregular ventricular rate, hypotension, and sympathetic discharge probably result in fractionation of the ventricular wavefront and VF. Also, digoxin increases the ventricular rate by shortening BT refractoriness. Lidocaine, for reasons that are unclear, has also been associated with degeneration of AF into VF. It is occasionally used in patients with WPW who have a wide QRS complex tachycardia that might be misinterpreted as VT. Unlike the IV route of administration, chronic oral amiodarone therapy can slow or block BT conduction.¹

Chronic Management

Symptomatic Patients With Concealed Bypass Tracts

Catheter ablation is considered first-line therapy (class I) for patients with paroxysmal SVT involving a concealed BT (i.e., orthodromic AVRT). However, because concealed BTs are not associated with an increased risk of SCD in these patients, catheter ablation can be presented as one of a number of potential therapeutic approaches, including pharmacological therapy and clinical follow-up alone. When pharmacological therapy is selected for patients with concealed BTs, it is reasonable to consider a trial of beta-blocker therapy, diltiazem, or verapamil (Fig. 18.8). These agents are effective for preventing recurrent tachycardia in approximately 50% of patients. Antiarrhythmic agents may be considered for patients with refractory tachycardia; however, the risk and benefits of these drugs should be carefully considered.¹

Symptomatic Patients With Manifest Bypass Tracts

Catheter ablation is considered the treatment of choice for patients with WPW syndrome—that is, patients with manifest preexcitation along with documented arrhythmias (antidromic or orthodromic AVRT or preexcited AF) or symptoms consistent with cardiac arrhythmias. Catheter ablation is curative in more than 95% of patients with a relatively low complication rate (about 3%), and it also obviates the unwanted side effects of pharmacological therapy.¹

For patients with WPW syndrome who are not candidates for, or prefer not to undergo catheter ablation, antiarrhythmic drugs to block BT conduction are considered (see Fig. 18.8). Class IC agents such as flecainide and propafenone (in patients without structural heart disease or ischemic heart disease), and class III drugs, such as sotalol and dofetilide, may be considered. Oral amiodarone is a last resort therapy, given the associated risks of long-term therapy. In general, antiarrhythmic drug therapy can offer symptomatic improvement in up to 90% of patients, although complete disappearance of symptoms is observed in only 30%.¹

Chronic oral beta-blocker, verapamil, and diltiazem may be used for the treatment of patients with WPW syndrome, particularly if their BT has been demonstrated to be incapable of rapid anterograde conduction. However, these agents must be used with caution and after a discussion with the patient concerning the potential risk of rapid conduction over the BT if AF develops. Digoxin, on the other hand, should be avoided because it can shorten the refractory period of the BT and, hence, is potentially harmful in patients with manifest BTs.¹

Asymptomatic Patients With Manifest Bypass Tracts

Asymptomatic young WPW patients have about 30% risk of becoming symptomatic, and a very small, but definite risk of life-threatening arrhythmias and SCD. Therefore, in the recent Pediatric and Congenital Electrophysiology Society (PACES) and the Heart Rhythm Society (HRS) expert consensus document on treatment of asymptomatic young WPW subjects, risk stratification is recommended to identify a potential subgroup of patients with BTs with “high-risk” properties that may confer an increased risk for lethal cardiac arrhythmias and in whom the risk-to-benefit ratio favors prophylactic ablation (Fig. 18.9).⁵

Initial risk stratification utilizes noninvasive testing (e.g., Holter monitoring, exercise stress testing) to ascertain true loss of preexcitation at physiological heart rates. Complete and abrupt loss of preexcitation during exercise testing or intermittent loss of preexcitation during ECG or ambulatory monitoring, indicate long anterograde ERP of the BT and help identify patients at low risk of rapid conduction over the BT and SCD (Box 18.1).^{5,15}

Inability to clearly demonstrate absolute loss of ventricular preexcitation on noninvasive testing warrants consideration for transesophageal

Drugs listed alphabetically. *pt*, Patient; *SHD*, structural heart disease (including ischemic heart disease). (From Page RL, Joglar JA, Caldwell MA, et al. 2015 ACC/AHA/HRS guideline for the management of adult patients with supraventricular tachycardia: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines and the Heart Rhythm Society. *J Am Coll Cardiol*. 2016;67:e27–e115.)

Fig. 18.9 Management Algorithm for Young Asymptomatic Patients With Wolff-Parkinson-White Electrocardiogram Pattern. ^aPatients unable to perform an exercise stress test should undergo risk stratification with an electrophysiological study. ^bPrior to invasive testing, patients and their parents/guardians should be counseled on the risks and benefits of proceeding with invasive studies, risks of observation only, and risks of medication strategy. ^cPatients participating at moderate- to high-level competitive sports should be counseled concerning the risk-benefit of ablation. ^dIn the absence of inducible atrial fibrillation, the shortest preexcited R-R interval determined by rapid atrial pacing is a reasonable surrogate. *SPERRI*, Shortest pre-excited R-R interval *SVT*, supraventricular tachycardia. (From Cohen MI, Triedman JK, Cannon BC, et al. PACES/HRS expert consensus statement on the management of the asymptomatic young patient with a Wolff-Parkinson-White [WPW, ventricular preexcitation] electrocardiographic pattern. *Heart Rhythm*. 2012;9:1006–1024.)

BOX 18.1 Findings Suggestive of Lower Risk of Life-Threatening Events in Wolff-Parkinson-White Patients

- Intermittent loss of the preexcitation pattern on ambulatory monitoring or serial electrocardiograms
- Abrupt and complete loss of preexcitation during exercise
- Loss of preexcitation after administration of sodium blockers
- Mean preexcited R-R interval >250 msec and shortest preexcited R-R >220 msec during atrial fibrillation
- Anterograde effective refractory period of the bypass tract <240 msec

or intracardiac EP testing. However, the benefits and risk of invasive risk stratification should be based on individual considerations such as age, gender, occupation, and athletic involvement, and should be thoroughly discussed with the patient or, in the case of a child, with the parents. Given the low risk associated with invasive EP testing (0.1% to 1%), it is reasonable to consider this approach for risk stratification in asymptomatic WPW patients. Several EP findings help identify high-risk patients who may benefit from catheter ablation, including: (1) shortest preexcited R-R interval less than 250 milliseconds during induced AF; (2) the presence of multiple BTs; (3) spontaneous degeneration of induced AVRT into preexcited AF; and (4) BT anterograde ERP less than 240 milliseconds.¹ The critical obligatory condition for VF is the presence of a short anterograde functional refractory period of the BT, which is best reflected in the shortest R-R interval between preexcited beats in AF.^{5,16} Although the ability to induce sustained AVRT has been considered by some as a potential risk factor, this has not been supported by recent studies.²

The role of isoproterenol challenge during EP testing has not yet been clearly defined. Isoproterenol administration can significantly shorten the shortest preexcited R-R interval and, as a result, increase the proportion of asymptomatic patients in the “high-risk” category. Thus some investigators suggested the use of a more stringent threshold for the shortest preexcited R-R interval (≤ 220 milliseconds) instead of the threshold adopted by the 2012 PACES/HRS Guidelines (≤ 250 milliseconds) for definition of “high-risk” BTs when EP testing is performed under the influence of isoproterenol.¹⁷

In low-risk patients, as determined by noninvasive or invasive testing, it is appropriate to pursue a strategy of follow-up with ECGs and reevaluation at selected intervals with a high degree of suspicion for new arrhythmia symptoms. This strategy should incorporate patient education about the potential risks associated with preexcitation and the symptoms of arrhythmias that should prompt them to seek medical attention. It is also advisable to give the patient a copy of his or her ECG and a short note about the fact that the WPW pattern is present to help prevent the misdiagnosis of MI and to explain the basis of cardiac arrhythmias in case they develop later. Importantly, WPW patients most susceptible to SCD are symptomatic. Thus the evolution of the clinical status from an asymptomatic state to symptoms (e.g., syncope or palpitations) likely portends a higher risk for SCD. Once WPW patients become symptomatic, catheter ablation may be considered, regardless of the prior risk assessment.⁵

In patients with high-risk BT characteristics, prophylactic catheter ablation is reasonable. A combination of inducible AVRT and short R-R interval during preexcited AF provides the best indication for ablation. Catheter ablation of the BT, regardless of BT characteristics, is also reasonable in asymptomatic patients with high-risk occupations (e.g., school bus drivers, police, and pilots), and is probably reasonable in: (1) patients involved in moderate- to high-intensity competitive

sports; (2) patients with structural heart disease; (3) patients with ventricular dysfunction secondary to dyssynchronous contractions; and (4) patients with BT locations associated with lower risk of procedural complications (such as AV block or coronary artery injury), which can counterbalance the potential benefit of ablation. However, because knowledge about the success and complication rates plays a major role in decision-making, the physician must consider his or her own success and complication rates for ablation of the specific location of the BT identified, and that information should be made available to the patient.⁵

It is important to recognize that the majority of adult patients with asymptomatic preexcitation have a benign course with few clinically significant arrhythmic events occurring over time; the risk of SCD is low, is seen mainly in children, and is rarely the initial clinical manifestation. Hence, observation without further evaluation or treatment remains a reasonable option in these patients, even when noninvasive low-risk markers are not evident. The key is a clear understanding by the patient of the relative merits of each strategy. The well-informed patient needs to choose between a very small risk of potentially life-threatening arrhythmia over a long period of time and a one-time small procedural risk associated with EP testing and catheter ablation. Certain patients such as athletes and those in higher risk occupations will generally choose ablation. Others, especially patients older than 30 years, may prefer the small risk of a conservative strategy.^{5,18}

It is important to note that both invasive and noninvasive EP markers, despite their high sensitivity and negative predictive value, lack specificity for identifying patients at risk of life-threatening ventricular arrhythmias, largely due to the very low incidence of SCD.⁷ The great majority of individuals with WPW, even with a shortest preexcited R-R interval less than 250 milliseconds during AF, will not experience SCD; thus the positive value of predicting SCD remains very low. Therefore the management of asymptomatic patients with a WPW pattern remains controversial.⁷

The ability of noninvasive risk stratification to identify low-risk patients is low (less than 20%). Hence, according to the 2012 PACES/HRS Guidelines, invasive EP evaluation would be recommended for the majority of young asymptomatic WPW patients, and the majority of those would undergo catheter ablation. A recent report retrospectively examined the consequences of following the published guidelines in 85 asymptomatic patients (less than 18 years old) with ventricular preexcitation ECG pattern persisting at peak exercise, to assess the outcomes of invasive risk stratification applying current guidelines. Approximately 38% of the patients exhibited adverse BT properties at EP study, fulfilling either the class IIA indication (shortest preexcited R-R interval less than 250 milliseconds during AF) or class IIB indication (AVRT inducibility) for catheter ablation. The use of isoproterenol infusion during EP testing shifted an additional 36% of those tested into one of these two indication classes. About 69% of young patients subjected to risk stratification underwent BT ablation as a result of the evaluated BT properties or patient/parental decision.^{17,19}

Although complications of a diagnostic EP study are generally minor and not life-threatening, the risks associated with an ablation procedure are likely at least similar to the risk of SCD in asymptomatic WPW patients. In three large series, procedure-related complications occurred in 1.8% to 8.2% of cases, and death as a consequence of ablation occurred in 0.07% to 0.19%.⁷ If routine EP testing were to be performed in the majority of asymptomatic WPW patients, many patients would proceed immediately to catheter ablation and, in others, there would be a strong temptation to ablate when catheters are in place (regardless of predicted SCD risk), especially given the fact that the criteria for ablation usually will not be black or white. This greatly increases the risk to the patient, which can potentially nullify the benefit of elimination of SCD risk achieved by BT ablation. A recent study using decision analysis software

to construct a risk-benefit decision tree for a target population of 20- to 40-year-old asymptomatic patients with WPW, found the decision to ablate resulted in a reduction of 10-year mortality risk of 8.8 patients for 1000 patients. The study suggested that it is necessary to treat 112 asymptomatic patients with WPW to save one life over 10 years.¹⁸

Finally, the physician and the patient must have a shared understanding of the value of invasive EP study for risk stratification, rather than as a therapeutic tool. These issues have to be resolved before proceeding with invasive measures, and the risks and benefits of proceeding with ablation of BT found not to have high-risk characteristics should be discussed thoroughly with patients in advance of the EP procedure.⁵

Wolff-Parkinson-White Patients and Sports Participation

WPW syndrome accounts for approximately 1% of deaths in athletes. Although many of the cases of SCD with WPW are associated with exercise, training does not alter the EP properties in WPW.

Catheter ablation is the treatment of choice for symptomatic WPW patients (whether or not engaged in athletics). For asymptomatic WPW patients engaged in moderate- to high-level competitive sports, non-invasive and, if needed, invasive risk stratification is advisable. For those with high-risk BT characteristics, ablation of the BT is recommended before clearance for competitive sports because of risk for life-threatening arrhythmias.^{5,20} In low-risk patients, as determined by noninvasive or invasive testing, BT ablation may still be appropriate, but competitive sports may be allowed without ablation, especially when BT ablation confers an unacceptable potential risk (e.g., AV block in the setting of midseptal or superoparaseptal BTs).^{5,20}

ELECTROCARDIOGRAPHIC FEATURES

Electrocardiography of Preexcitation

Anterogradely conducting AV BTs produce the classic WPW ECG pattern characterized by a fusion between conduction via the BT and the normal AVN-HPS: (1) short PR (P-delta) interval (less than 120 milliseconds); (2) slurred upstroke of the QRS (delta wave); and (3) wide QRS (>120 milliseconds) (see Figs. 18.1 and 18.2).^{13,14}

The degree of preexcitation depends on several factors, including conduction time over the AVN-HPS, conduction time from the sinus node to the atrial insertion site of the BT (which depends on the distance, conduction, and refractoriness of the intervening atrial tissue), and conduction time through the BT (which depends on the length, thickness, and conduction properties of the BT).

Pharmacological and/or physiological maneuvers that alter AVN conduction (e.g., carotid sinus massage, Valsalva maneuvers, adenosine, beta-blockers) can be used to alter the degree of preexcitation, thereby confirming the diagnosis of the presence of an anterogradely conducting AV BT.

The ECG pattern displayed by some patients with WPW syndrome can simulate the pattern found in other cardiac conditions and can alter the pattern seen in the presence of other cardiac disease. A negative delta wave (presenting as a Q wave) can mimic a myocardial infarction (MI) pattern. Conversely, a positive delta wave can mask the presence of a previous MI. Intermittent WPW can also be mistaken for frequent premature ventricular complexes (PVCs) (Fig. 18.10). If the WPW pattern persists for several beats, the rhythm can be misdiagnosed as an accelerated idioventricular rhythm or, if sufficiently rapid, VT. The

Fig. 18.10 Preexcitation Alternans. Surface electrocardiogram during sinus tachycardia demonstrating intermittent preexcitation in which a QRS complex manifesting a delta wave (red arrow) alternates with a normal QRS complex (blue arrow) (i.e., preexcitation alternans). Note the intermittent abrupt loss of delta wave associated with prolongation of the PR interval and the presence of a stable sinus rate, indicating that loss of preexcitation is secondary to anterograde block in the bypass tract (i.e., intermittent preexcitation) rather than enhanced atrioventricular nodal conduction.

WPW pattern is occasionally seen on alternate beats and may suggest ventricular bigeminy. An alternating WPW and normal pattern can occasionally suggest electrical alternans. On the other hand, late-coupled PVCs (eFig. 18.2) and ventricular pacing (eFig. 18.3) with inapparent pacing artifacts can occasionally mimic ventricular preexcitation.

Inapparent Versus Intermittent Preexcitation

Inapparent preexcitation. With inapparent preexcitation, preexcitation is absent on the surface ECG despite the presence of an anterogradely conducting AV BT because conduction over the AVN-HPS reaches the ventricle faster than that over the BT. In this setting, the PR interval is shorter than the P-delta interval would be if preexcitation were present. Therefore the transition from manifest to inapparent preexcitation is characterized by normalization of the QRS in conjunction with *shortening* of the PR interval, reflecting the now better AVN-HPS conduction.

Inapparent preexcitation is usually caused by: (1) enhanced AVN conduction, so that it is faster than conduction over the BT; (2) prolonged intraatrial conduction from the site of atrial stimulation to the atrial insertion site of the BT (most often left lateral), favoring antero-grade conduction and depolarization of the ventricle over the AVN-HPS; or (3) prolonged conduction over the BT, so that it is slower than AVN-HPS conduction.

Intermittent preexcitation. Intermittent preexcitation is defined as the presence and absence of preexcitation on serial ECGs or ambulatory cardiac monitoring (Fig. 18.11). True intermittent preexcitation is characterized by an abrupt loss of the delta wave (regardless of how fast or slow AVN conduction is), with *prolongation* (normalization) of the PR interval (reflecting the loss of the faster BT conduction, and the

subsequent conduction over the slower AVN), and normalization of the QRS in the absence of any significant change in heart rate.^{13,14}

The mechanism of intermittent preexcitation is poorly understood, but is likely related to the BT refractory period and cellular connectivity within the BT. Potential mechanisms include (1) phase 3 (i.e., tachycardia-dependent) or phase 4 (i.e., bradycardia-dependent) block in the BT (see Chapter 10); (2) anterograde or retrograde concealed conduction produced by PVCs, premature atrial complexes (PACs), or atrial arrhythmias; (3) BTs with a long ERP and the gap phenomenon in response to PACs; and (4) BTs with a long ERP and supernormal conduction.

Preexcitation alternans is a form of intermittent preexcitation in which a QRS complex manifesting a delta wave alternates with a normal QRS complex (see Fig. 18.10). **Concertina preexcitation** is another form of intermittent preexcitation in which the PR intervals and QRS complex durations show a cyclic pattern; that is, preexcitation becomes progressively more prominent over a number of QRS complex cycles followed by a gradual diminution in the degree of preexcitation over several QRS cycles, despite a fairly constant heart rate.

Differentiation between intermittent preexcitation and inapparent preexcitation on an ECG showing QRS complexes with and without preexcitation can be achieved by comparing the P-delta interval during preexcitation and the PR interval when preexcitation is absent. Loss of preexcitation associated with a PR interval longer than the P-delta interval is consistent with intermittent preexcitation (see Fig. 18.11), whereas loss of preexcitation associated with a PR interval shorter than the P-delta interval is consistent with inapparent preexcitation. Furthermore, maneuvers that slow AVN conduction (e.g., carotid sinus massage, AVN blockers) would unmask inapparent preexcitation but would not affect intermittent preexcitation.

Fig. 18.11 Intermittent Preexcitation. Surface electrocardiogram leads II and V1 and intracardiac recordings in a patient with Wolf-Parkinson-White syndrome and a right anterior bypass tract (BT). Note the intermittent abrupt loss of delta wave (stars) associated with prolongation of the PR interval and normalization of the His bundle–ventricular interval, despite the presence of a constant atrial–His bundle (AH) interval (atrioventricular node [AVN] conduction) and a stable sinus rate, indicating that loss of preexcitation is secondary to antero-grade block in the BT (i.e., intermittent preexcitation) rather than enhanced AVN conduction. A, Atrial electrogram; CS_{dist}, distal coronary sinus; CS_{prox}, proximal coronary sinus; H, His bundle potential; HRA, high right atrium; RVA, right ventricular apex.

eFig. 18.2 Late-Coupled Premature Ventricular Complexes (PVCs) Mimicking Intermittent Ventricular Preexcitation. Surface electrocardiogram of normal sinus rhythm with late-coupled PVCs, which are inscribed shortly after the sinus P waves, resulting in a short PR interval and wide QRS complexes mimicking intermittent ventricular preexcitation. Note that the degree of widening of the QRS and the variability of the QRS morphology and the varying relationship to the preceding P waves all argue against ventricular preexcitation.

eFig. 18.3 Ventricular Pacing Mimicking Ventricular Preexcitation. Surface electrocardiogram (ECG) of normal sinus rhythm with atrial-tracking ventricular pacing. The QRS complexes are the result of fusion from ventricular pacing and conduction over the normal atrioventricular conduction axis, resulting in a pseudo-delta wave, mimicking a Wolf-Parkinson-White ECG pattern. The pacing artifacts are very small, but careful inspection reveals those artifacts most clearly in lead III.

Supraventricular Tachyarrhythmias Associated With Wolff-Parkinson-White Syndrome

Orthodromic Atrioventricular Reentrant Tachycardia

The ECG during orthodromic AVRT shows retrograde P waves inscribed within the ST-T wave segment with an RP interval that is usually less than half of the tachycardia R-R interval (i.e., RP interval < PR interval) (Fig. 18.12). The RP interval remains constant, regardless of the tachycardia cycle length (TCL), because it reflects nondecremental retrograde conduction over the BT. QRS morphology during orthodromic AVRT is generally normal and not preexcited, even when preexcitation is present during NSR (see Fig. 18.5). Functional bundle branch block (BBB) can be observed frequently during orthodromic AVRT at fast rates (see Fig. 18.12). The presence of BBB during SVT in a young person (less than 40 years) should raise the suspicion of orthodromic AVRT incorporating a BT ipsilateral to the blocked bundle, because the longer conduction time through the involved ventricle engendered by the BBB facilitates orthodromic reentry by enabling all portions of the circuit enough time to recover excitability from the prior cycle. This is particularly true with left bundle branch block (LBBB), which is very uncommon in younger patients.

Orthodromic AVRT tends to be a rapid tachycardia, with rates ranging from 150 to more than 250 beats/min, generally faster in younger people. A beat-to-beat oscillation in QRS amplitude (QRS alternans) is present in up to 38% of cases and is most commonly seen when the rate is very rapid (Fig. 18.13). The mechanism for QRS alternans is not clear but may partly result from oscillations in the relative refractory period of the distal portions of the HPS.

Ischemic-appearing ST segment depression also can occur during orthodromic AVRT, even in young individuals who are unlikely to have coronary artery disease. An association has been observed between repolarization changes (ST segment depression or T wave inversion) and the underlying mechanism of the tachycardia because such changes are more common in orthodromic AVRT than AVNRT (57% vs. 25%). Several factors can contribute to ST segment depression in these arrhythmias, including changes in autonomic tone, intraventricular conduction disturbances, a longer VA interval, and a retrograde P wave of longer duration that overlaps into the ST segment.²¹ The location of the ST segment changes can vary with the location of the BT; ST segment depression in leads V3 to V6 is almost invariably seen with a left lateral BT, whereas ST segment depression and a negative T wave in the inferior leads is associated with a posteroseptal or posterior BT. A negative or notched T wave in leads V2 or V3 with a positive retrograde P wave in at least two inferior leads suggests an anteroseptal BT. However, ST segment depression occurring during orthodromic AVRT in an older patient mandates consideration of possible coexisting ischemic heart disease.

Antidromic Atrioventricular Reentrant Tachycardia

Antidromic AVRT is characterized by a wide (fully preexcited) QRS complex, usually regular R-R intervals, and ventricular rates of up to 250 beats/min (see Fig. 18.5). The width of the preexcited QRS complex and the amplitude of the ST-T wave segment usually obscure the retrograde P wave on the surface ECG. When the P waves can be identified, they are inscribed within the ST-T wave segment with an RP interval that may be more than half of the tachycardia R-R interval because retrograde conduction occurs slowly via the AVN-HPS. The PR (P-delta) interval remains constant, regardless of the TCL, because it represents nondecremental anterograde conduction over the BT.

Permanent Junctional Reciprocating Tachycardia

PJRT tends to be incessant, stopping and starting spontaneously every few beats without initiating PACs or PVCs. The heart rate is usually

between 120 and 200 beats/min and the QRS duration is generally normal. Slow retrograde conduction over the BT causes the RP interval during PJRT to be long, usually more than half of the tachycardia R-R interval (Fig. 18.14). The P waves resulting from retrograde conduction are easily seen on the ECG and are inverted in leads II, III, aVF, and V3 to V6.

Atrioventricular Nodal Reentrant Tachycardia and Atrial Tachycardia

Both AVNRT and AT can be associated with partially or fully preexcited QRS complex secondary to anterograde conduction to the ventricles over the bystander BT. When AVNRT occurs in the WPW syndrome, the arrhythmia can be difficult to distinguish from orthodromic AVRT without EP testing.

Atrial Fibrillation

There are several characteristic findings on the ECG in patients with AF conducting over a BT, so-called preexcited AF. The rhythm is irregularly irregular, and can be associated with very rapid ventricular response caused by the nondecremental anterograde AV conduction over the BT (Fig. 18.15). However, a sustained rapid ventricular rate of more than 180 to 200 beats/min will often create R-R intervals that appear to be regular when the ECG is recorded at 25 mm/s. Although the QRS complexes are conducted aberrantly, resembling those during preexcited NSR, their duration can be variable and they can become normalized. This is not related to the R-R interval (i.e., it is not a rate-related phenomenon), but rather is related to the variable relationship between conduction over the BT and AVN-HPS. Preexcited and normal QRS complexes often appear “clumped.” This can result from concealed retrograde conduction into the BT or the AVN (Fig. 18.16).

The QRS complex during preexcitation is a fusion between the impulse that preexcites the ventricles caused by rapid conduction through a BT and the impulse that takes the usual route through the AVN. The number of impulses that can be transmitted through the BT and the amount of preexcitation depend on the refractoriness of the BT and AVN. The shorter the anterograde ERP of the BT, the more rapid is the anterograde impulse conduction over the BT and, because of more preexcitation, the wider the QRS complexes. Patients who have a BT with a very short ERP and rapid ventricular rates represent the group at greatest risk for development of VF.

Anterograde block in the BT during AF abolishes retrograde concealment into the AVN, which in turn allows the AVN to recover its excitability and conduct anterogradely. In turn, these conducted impulses through the AVN can result in retrograde concealment into the BT, causing anterograde block of the BT and, thereby, slowing the ventricular rate.

Atrial Flutter

AFL, like AF, can conduct anterogradely via a BT resulting in a preexcited tachycardia. Depending on the various refractory periods of the normal and pathological AV conduction pathways, AFL can potentially conduct 1:1 to the ventricles during a preexcited tachycardia, making the arrhythmia difficult to distinguish from VT (see Fig. 12.10).

Electrocardiographic Localization of the Bypass Tract

Careful analysis of the preexcitation pattern during NSR can potentially allow an accurate approximation of the location of the BT. This provides the electrophysiologist with important information that can guide patient counseling regarding the risks and benefits of ablation. In particular, it provides some guidance about the proximity of the BT to the normal conduction system and the subsequent risk of AV block associated with an ablation attempt, as well as the need for left heart catheterization

Fig. 18.12 Orthodromic Atrioventricular Reentrant Tachycardia (AVRT) Using a Concealed Superoparaseptal Bypass Tract (BT). Note the P waves (arrows) inscribed within the ST-T wave segment (short RP interval). Ischemic-appearing ST segment depression is also observed. Functional right bundle branch block occurs in the right side of the tracing, with prolongation of the RP (ventriculoatrial [VA]) interval, suggesting that retrograde VA conduction during the supraventricular tachycardia is mediated by a right-sided BT. The dashed lines denote the QRS onset and P wave onset.

Fig. 18.13 Electrocardiogram (ECG) of Orthodromic Atrioventricular Reentrant Tachycardia Showing QRS Alternans in Multiple ECG Leads.

Fig. 18.14 Surface Electrocardiogram (ECG) of Permanent Junctional Reciprocating Tachycardia (PJRT). Note the incessant nature of the arrhythmia, stopping and starting spontaneously every few beats without initiating atrial or ventricular ectopic beats. Slow retrograde conduction over the bypass tract causes the RP interval during PJRT to be long (long RP tachycardia). The P waves resulting from retrograde conduction are easily seen on the ECG and are inverted in the inferior leads.

and atrial septal puncture and their potential complications. In addition, it can help in planning the ablation procedure, such as the use of cryoablation for septal BTs or the need for special equipment for atrial septal puncture for left-sided BTs.

Localization Using the Delta Wave

Delta wave morphology reflects the ventricular insertion site of the BT and, hence, is helpful in approximating the BT location, especially when

maximal preexcitation is present. However, during NSR, only partial ventricular preexcitation is usually observed, which limits the accuracy of BT localization based on the surface ECG. In addition, the degree of preexcitation can vary in an individual, depending on heart rate, autonomic tone, and AVN function, as well as the location and EP characteristics of the BT. Therefore it is important first to assess the degree of preexcitation visible throughout the entire ECG and then use only delta wave polarity for localization (the first 20 to 60 milliseconds

Sinus rhythm with ventricular preexcitation

Preexcitation atrial fibrillation

Fig. 18.15 Electrocardiogram of Sinus Rhythm Atrial Fibrillation With Ventricular Preexcitation. Ventricular preexcitation by the same right superoparaseptal bypass tract. Note the fast ventricular rate during preexcited atrial fibrillation (exceeding 100 beats/min).

Fig. 18.16 Preexcited Atrial Fibrillation. Note the “clumping” of preexcited and normal QRS complexes, likely due to concealed retrograde conduction into the bypass tract or the atrioventricular node.

of the QRS in most cases, unless fully preexcited) rather than the overall QRS polarity, which may vary from each other.

Several algorithms have been developed to predict the anatomic location of manifest BTs based on delta wave polarity on the surface ECG (Box 18.2; Figs. 18.17–18.20). Although these algorithms facilitate prediction of the location of a BT, they are inherently limited by biological variability in anatomy (e.g., rotation of the heart within the thorax), variable degree of preexcitation and QRS fusion, the presence of more than one manifest BT, intrinsic ECG abnormalities (such as prior MI and ventricular hypertrophy), patient body habitus, and technical variability in ECG acquisition and electrode positioning. The accuracy of these algorithms in more recent studies has not reached the accuracy previously reported by their designers.²² Therefore these algorithms should be regarded as an orientation rather than a precise localization tool. No single published algorithm offers extremely high sensitivity and specificity for all BT locations. The algorithms appear most accurate in predicting left free-wall BT locations and least accurate in predicting midseptal or right anteroseptal BT locations. Hence, it may be more realistic to initially identify a general area in which the BT is located, and then to apply more subtle criteria from one or more of the algorithms to attempt a more precise localization. This can be achieved by applying some basic rules while maintaining a mental 3-D representation of the mitral and tricuspid annuli and their anatomical relationships to adjacent structures as they lie within the chest (i.e., “attitudinally correct orientation”) while analyzing the ECG and predicting morphology of the preexcited QRS.

Of note, the mere presence and the degree of preexcitation can sometimes help in predicting the location of the BT. Posteroseptal and right-sided BTs tend to be associated with a prominent degree of preexcitation because of the proximity to the sinus node, whereas left lateral BTs are often associated with subtle preexcitation. Nevertheless, when preexcitation is prominent, the accuracy of surface ECG localization of manifest BTs tends to be higher for the diagnosis of left free-wall BTs than for BTs in other locations.

On the surface ECG, analysis of delta wave polarity and amplitude progression in precordial leads, and frontal plane horizontal and vertical axes, are valuable for predicting the site of origin of manifest BTs (Fig. 18.21).

Precordial transition. Lead V1 is a unipolar lead positioned at the right anterior chest wall. Therefore, as the BT location shifts progressively more to the left or posteriorly, the precordial transition (i.e., the first precordial lead where the R wave amplitude exceeds the S wave amplitude) becomes sequentially earlier, thereby transforming the precordial preexcited QRS morphology from a late transition LBBB pattern of the preexcited QRS to a positively concordant right bundle branch block (RBBB) pattern. Hence, left-sided BTs exhibit positive delta waves in lead V1, while right-sided BTs exhibit negative delta waves. The farther the BT is to the left or posteriorly on the mitral annulus, the larger the positive delta wave, and the farther the BT is to the right along the tricuspid annulus, the deeper the negative delta wave is in lead V1.

Frontal plane horizontal axis. Lead I primarily reflects the horizontal axis. BTs closer to the left axilla will produce a deeply negative

BOX 18.2 Delta Wave Characteristics During Preexcitation According to Bypass Tract Location^a**Left Lateral/Left Anterolateral BTs**

- A. R/S ≥ 1 in V2 and positive delta in III, or R/S < 1 in V2 and positive delta in III and V1
- B. RS transition $\leq V1$ and > 2 positive delta in the inferior leads or S $>$ R in aVL
- C. QS or QR morphology in aVL and no negative QRS in III and V1

Left Posterior/Left Posterolateral BTs

- A. R/S ≥ 1 in V1 and V2, no positive delta in III and positive delta in V1
- B. R/S transition $\leq V1$, no ≥ 2 positive delta in the inferior leads, no S $>$ R in aVL, in lead I R $<$ (S 0.8 mV), and the sum of the inferior delta is not negative
- C. Positive QRS in aVL and an equiphasic QRS or positive in V1 and no negative QRS in III

Left Posteroseptal BTs

- A. R/S ≥ 1 in V2, no positive delta in III, and positive delta and R/S < 1 in V1
- B. R/S transition $\leq V1$, no ≥ 2 positive delta in the inferior leads, no S $>$ R in aVL, in lead I R $<$ (S 0.8 mV), and the sum of the inferior delta is negative
- C. Negative QRS in III, V1, and aVF, tallest precordial R wave in V2–V4 and R wave width in V1 > 0.06 msec

Midseptal BTs

- A. R/S < 1 in V2, no positive delta in III, and negative delta in V1
- B. R/S transition between V2 and V3 or between V3 and V4 but the delta amplitude in lead II ≥ 1.0 mV (septal location), and the sum of delta polarities in inferior leads is -1 , 0 , or $+1$ mV
- C. Negative QRS in leads III, V1, and aVF, tallest precordial R in leads V2–V4 and R wave width in V1 < 0.06 msec

Right Posteroseptal BTs

- A. R/S ≥ 1 in V2 and no positive delta in III and V1
- B. The sum of delta polarities in inferior leads is less than or equal to -2 mV
- C. Negative QRS in leads III, V1, and aVF and tallest precordial R in V5 or V6

Right Posterior/Right Posterolateral BTs

- A. R/S < 1 in V2, no positive delta in III and no negative delta in V1, and negative delta polarity in aVF
- B. R/S transition between V3 and V4 with delta amplitude in lead II < 1.0 mV or $\geq V4$ and the delta axis is < 0 degrees and the R in lead III is ≤ 0 mV
- C. Positive QRS in III, negative in V1, and RS morphology in aVL

Right Lateral/Right Anterolateral BTs

- A. R/S < 1 in V2, no positive delta in III and no negative delta in V1 and negative or biphasic delta in aVF
- B. R/S transition between leads V3 and V4 with delta amplitude in lead II < 1.0 mV or $> V4$ and the delta axis is < 0 degrees and the R amplitude in lead III is < 0 mV
- C. Positive QRS in leads aVL and III and negative in V1

Right Anterior/Right Superoparaseptal BTs

- A. R/S < 1 in V2, positive delta in III and no positive delta in V1
- B. The sum of delta polarities in inferior leads is ≥ 2
- C. Positive QRS in aVF and negative in leads III and V1

complex in lead I (i.e., rightward axis). Conversely, BTs closer to the right axilla are strongly positive in lead I (i.e., leftward axis). Leads II/aVL and III/aVR also have net leftward and rightward vectors, respectively. Hence, as the BT location moves progressively to the left (e.g., from anterior to lateral mitral annulus), the delta wave assumes progressively less positive/more negative deflection in lead I, a taller R wave in lead III than in lead II, and a larger S wave in lead aVL compared to lead aVR. Opposite changes are expected as the BT location moves progressively to the right (from anteromedial to lateral tricuspid annulus).

Frontal plane vertical axis. The inferior leads (II, III, and aVF) reflect the vertical axis. Therefore BTs located at the superior aspect of the tricuspid or mitral annulus exhibit positive deflections in the inferior

leads (i.e., vertical axis). The magnitude of the inferiorly directed vector diminishes as the site of origin shifts from superior to inferior regions of either annulus.

Left vs. right free-wall BTs. Delta wave polarity in right precordial leads is most helpful in distinguishing between right- and left-sided free-wall BTs. Ventricular activation originating from the right ventricle (RV) (as mediated by right-sided BTs) is expected to produce a predominantly negative deflection in right precordial leads, whereas more posterior or left-sided sites of origin produce more positive deflections. Hence, an R/S ratio greater than 1 or a dominant R wave in lead V1 is consistent with left-sided BTs, whereas R/S transition after lead V2 suggests right-sided BTs. When the R/S transition is at lead V2 or between

leads V1 and V2, the R/S wave in the left lateral limb leads (I and aVL) favors right-sided BTs, otherwise left-sided BTs are likely.

Left-sided BTs. All left free-wall BTs exhibit positive delta wave polarity in the right precordial leads, an R/S ratio greater than 1, or a dominant R wave in lead V1. Because of its superior location in the

IV, BTs originating from the anterior mitral annulus exhibit larger R wave amplitudes in the inferior leads. As the BT location shifts progressively more laterally, R wave amplitude becomes progressively larger in lead III and smaller in lead II. The delta wave amplitude ratio in leads III/II is greater than 1 for posterolateral BTs and less than 1 for anterolateral BTs. BTs located at the inferior aspects of the mitral annulus exhibit negative delta waves in the inferior leads. Furthermore, BT locations at the lateral aspect of the mitral annulus produce a more negative delta wave in the left lateral limb leads (aVL and I) than anterior or posterior annular locations. In fact, a negative delta wave in the left lateral leads (aVL, I, and V6) is pathognomonic of a left lateral BT.

Right-sided BTs. BTs arising from the tricuspid annulus demonstrate negative delta wave polarity in the right precordial leads and positive polarity in leads V5 and V6. As the BT location moves from medial/septal to lateral locations along the tricuspid annulus, the precordial transition becomes later (at lead V3 in septal locations, and after lead V3 in free-wall locations) and the negative delta wave becomes deeper in anterior precordial leads (V1 to V3). Right-sided BTs typically display a large positive delta wave in the left lateral limb leads (aVL and I), but a predominantly negative delta wave in lead aVR. Delta wave polarity in the inferior leads is positive in anterior annular BTs. As the BT location moves laterally and inferiorly, the delta wave becomes more negative in the inferior leads. Positive delta waves in leads II and aVF are consistent with anteroseptal locations, whereas negative delta waves in the inferior leads suggest posteroseptal locations. Flat or biphasic delta waves suggest midseptal locations.

Fig. 18.21 Delta Wave Morphology on the Surface Electrocardiogram (ECG) During Ventricular Preexcitation. Representative surface 12-lead ECG of delta wave morphology (*top panels*) with the corresponding location of the successful ablation site around the valvular annulus on an anatomic illustration (*bottom*). (A) left anterolateral (LAL); (B) left lateral (LL); (C) left posterolateral (LPL); (D) left posterior (LP); (E) left posteroseptal (LPS); (F) right posteroseptal (RPS); (G) midseptal (MS); (H) right anteroseptal (superoparaseptal, RAS); (I) right lateral (RL). MV, Mitral valve; TV, tricuspid valve. (Anatomic illustration of mitral and tricuspid annuli is shown at the bottom [from Netter Images {www.netterimages.com} with permission].)

Anteroseptal BTs. Right superoparaseptal (anteroseptal) BTs connect the RA and RV free walls at the anteromedial aspect of the tricuspid annulus. Because of its relatively superior and anterior ventricular insertion compared to the rest of the ventricular mass, these BTs exhibit positive delta waves in the inferior leads (II, III, and aVF). In addition, delta waves are often negative in leads V1 and V2, but slightly positive ($R/S < 1$) delta waves also are observed. Similar to right free-wall BTs, delta waves are typically positive in leads I and aVL and negative in lead aVR.

Midseptal BTs. The delta wave is positive in lead II, predominantly negative in lead III, and negative or isoelectric in lead aVF. The delta wave in lead V1 is usually negative and R/S transition occurs after lead V2 (usually between leads V2 and V3). However, variations are not infrequent, especially in the inferior leads and in V2. Midseptal BTs can be differentiated from superoparaseptal and para-Hisian BTs by a negative delta wave in lead III, a biphasic delta wave in lead aVF, and a larger R/S ratio in lead V2, likely due to the posterior location of the AV septum compared to the anterior tricuspid annulus.²³

Posteroseptal BTs. Posteroseptal BTs are characterized by a deeply negative delta wave in lead III. The delta wave is often negative in lead aVF, especially for right posteroseptal BT locations. A negative delta wave in lead II predicts an epicardial location of the posteroseptal BT. The delta wave in lead V1 can be negative, isoelectric, or positive. Lead V2 typically displays a positive delta wave, with the R wave larger than the S wave. A negative delta wave polarity in lead V1 with abrupt transition to positive polarity (with R/S ratio greater than 1) in lead V2 favors a right-sided location of the posteroseptal BT, whereas left posteroseptal BTs are often associated with biphasic or positive delta wave polarity in leads V1 and V2. An R/S ratio greater than 1 in lead V1 is a more accurate marker of left posteroseptal BTs. The tallest precordial R wave is typically recorded in the midprecordial leads (V2 to V4) in left posteroseptal BTs, and in the lateral precordial leads (V5 or V6) in right posteroseptal BTs.

Localization Using Polarity of the Retrograde P Wave Morphology

The polarity of the retrograde P waves during orthodromic AVRT is dependent on the location of the atrial insertion of the BT, and is helpful in localizing the BT. However, the P wave is usually inscribed within the ST segment and its morphology may not be easily determined.^{24,25}

In general, P wave morphology in leads I and V1 and in the inferior leads is most helpful (Fig. 18.22). A negative P wave vector in lead I is highly suggestive of left free-wall BTs, whereas a positive vector is suggestive of right free-wall BTs. On the other hand, a negative P wave in lead V1 predicts right-sided BTs. P wave polarity in the inferior leads, positive or negative, suggests superior or inferior location of the BT, respectively.^{24,25}

Left free-wall BTs have positive P waves in lead V1 and negative P waves in leads I and aVL. If the retrograde P wave is negative in all three inferior leads, the BT is located at the inferoposterior mitral annulus. As the BT location moves to the lateral mitral annulus, the P wave becomes isoelectric or biphasic in one of the three inferior leads. The P wave becomes positive in all inferior leads for left anterior/anterolateral BTs. Thus, as the BT moves from posterior to anterior locations along the mitral annulus, the positive P wave is seen initially in lead III, followed by lead aVF and lead II.^{24,25}

For right free-wall BTs, the P wave is negative in lead V1 and positive or isoelectric in lead I. If the P wave is positive in all inferior leads, the BT is located in the anterior wall. If the P wave is negative in all inferior leads, the BT is located in the posterior wall. However, moving from the posterior to the anterior location, the positive P wave is seen initially in lead II, followed by lead aVF and lead III.²⁴

Posteroseptal BTs display positive P waves in leads V1, aVR, and aVL, and isoelectric or biphasic P waves in lead I. P waves are negative in all inferior leads (II, III, aVF). Left posterior BTs also have negative P waves in the inferior leads, but the P waves are more negative in lead II than in lead III and are more positive in lead aVR than in lead aVL. Discrimination between left and right posteroseptal BTs based on P wave morphology is limited. In contrast, anteroseptal BTs display positive P waves in inferior leads and biphasic P waves in lead V1.²⁴

ELECTROPHYSIOLOGICAL TESTING

EP testing is used to study the features, location, and number of BTs and the tachycardias, if any, associated with them (Box 18.3). Typically, three quadripolar catheters are positioned in the high RA, RV apex or septum, and HB region, and a decapolar catheter is positioned in the CS (see Fig. 4.4). If a right-sided BT is suspected, a duo-decapolar (Halo) catheter along the tricuspid annulus can be helpful.

Some investigators have advocated a simplified approach to ablation using only one or two catheters. Although often successful, 10% of patients with preexcitation have multiple arrhythmias, and 10% to 20% of such patients have multiple BTs that can result in a very complex procedure. Because it is difficult to know beforehand in any given patient whether the procedure will be straightforward or complex, the single-catheter approach to ablation of arrhythmias should be discouraged.²⁶

Baseline Observations During Sinus Rhythm

Ventricular preexcitation is associated with a short His bundle–ventricular (HV) or H-delta interval during NSR. The HV interval can even be negative or the His potential can be buried in the local ventricular electrogram. The QRS is a fusion between conduction over the BT and that over the AVN-HPS. The site of earliest ventricular activation is near the ventricular insertion site of the BT (i.e., near the tricuspid annulus or mitral annulus at the base of the heart). Slowing of conduction in the AVN by carotid sinus massage, AVN blockers, or rapid atrial pacing unmasks and increases the degree of preexcitation, because these maneuvers do not affect the conduction over the BT. Dual AVN pathways are present in 8% to 40% of patients.

Programmed Atrial Stimulation During Sinus Rhythm

In the presence of a manifest AV BT, atrial stimulation from any atrial site can help unmask preexcitation if it is not manifest during NSR because of fast AVN conduction. Incremental rate atrial pacing and progressively premature AES produce decremental conduction over the AVN (but not over the BT), increasing the degree of preexcitation and shortening the HV interval, until the His potential is inscribed within

BOX 18.3 Goals of Electrophysiological Evaluation in Patients With Wolff-Parkinson-White Syndrome

- Confirming the presence of an atrioventricular BT
- Evaluation for the presence of multiple BTs
- Localization of the BT(s)
- Evaluation of the refractoriness of the BT and its implications for life-threatening arrhythmias
- Induction and evaluation of tachycardias
- Demonstration of the BT role in the tachycardia
- Evaluation of other tachycardias not dependent on the presence of the BT
- Termination of the tachycardias

BT, Bypass tract.

Fig. 18.22 Stepwise Algorithm for Predicting Bypass Tract Location Based on Retrograde P Wave Morphology During Orthodromic Atrioventricular Reentrant Tachycardia. The accuracy of the algorithm is indicated based on results of a prospective study in 164 patients. The denominator is the total number of patients in that group; the numerator is the number of patients with correct predictions. A new electrocardiographic algorithm using retrograde P waves for differentiating atrioventricular node reentrant tachycardia from atrioventricular reciprocating tachycardia mediated by concealed accessory pathway. *J Am Coll Cardiol.* 1997;29:394–402.)

the QRS. The His potential remains activated anterogradely over the AVN until anterograde block in the AVN occurs; the QRS then becomes fully preexcited, and the His potential becomes retrogradely activated (Fig. 18.23).

Atrial stimulation close to or at the AV BT insertion site results in maximal preexcitation and the shortest P-delta interval because of the lack of intervening atrial tissue whose refractoriness may otherwise limit the ability of atrial stimulation to activate the AV BT as early (Fig. 18.24). Atrial pacing can reveal the presence of multiple BTs (eFig. 18.4). Rare cases of catecholamine-dependent BTs have been reported that require isoproterenol infusion to manifest preexcitation that is absent at baseline.

The failure of atrial stimulation to increase the amount of preexcitation can be caused by: (1) markedly enhanced AVN conduction; (2) the presence of another AV BT; (3) pacing-induced block in the AV BT because of a long ERP of the BT (longer than that of the AVN); (4) total preexcitation already present at the basal state caused by prolonged or absent AVN-HPS conduction; (5) decremental conduction in the BT; or (6) the presence of a fasciculoventricular BT rather than an AV BT.

Programmed Ventricular Stimulation During Sinus Rhythm

eFig. 18.4 Atrial Pacing in the Presence of Two Bypass Tracts (BTs). Surface electrocardiogram and intracardiac recordings during coronary sinus pacing (S) in a patient with both right and left lateral BTs. The first two complexes show a left lateral preexcitation pattern (*red arrows*), whereas this pathway fails to conduct on the last two complexes, which show a right lateral preexcitation pattern (*blue arrows*). *CS_{dist}*, Distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *His_{dist}*, distal His bundle; *His_{mid}*, middle His bundle; *His_{prox}*, proximal His bundle; *HRA*, high right atrium; *RVA*, right ventricular apex.

Fig. 18.23 Effect of Atrial Extrastimulation (AES) on Preexcitation. (A) Preexcitation is manifest during normal sinus rhythm and atrial pacing associated with a short His bundle–ventricular (HV) interval (–11 milliseconds). AES produces decremental conduction over the atrioventricular node (AVN) (with prolonged atrial–His bundle interval) but not over the bypass tract (constant P–delta interval), increasing the degree of preexcitation with the His potential inscribed within the QRS (HV interval of –64 milliseconds). (B) An earlier coupled AES produces more pronounced preexcitation and an HV interval of –93 milliseconds. (C) A more premature AES produces full preexcitation with the His bundle activated retrogradely (*H'*), followed by ventriculoatrial conduction over the AVN and an echo beat (atrioventricular reentry). *A*, Atrial electrogram; *CS_{dist}*, distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *H*, His bundle potential; *HRA*, high right atrium; *RVA*, right ventricular apex.

Effect of site of pacing on preexcitation

Fig. 18.24 Effect of Site of Pacing on Preexcitation. (A) In the presence of a manifest left lateral bypass tract (BT), pacing from the high right atrium at a cycle length (CL) of 600 milliseconds produces minimal preexcitation. The degree of preexcitation increases with premature stimulation because of delay in atrio-ventricular nodal conduction. (B) In the same patient, pacing at the same CLs from the distal coronary sinus, close to or at the BT insertion site, results in a larger degree of preexcitation and shorter P-delta interval because of the lack of intervening atrial tissue whose refractoriness might otherwise limit the ability of atrial stimulation to activate the BT as early. *CS_{dist}*, Distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *HRA*, high right atrium; *RVA*, right ventricular apex.

ventricular extrastimulation (VES) is a gradual delay of VA conduction (manifest as gradual prolongation of the VA and His bundle–atrial [HA] intervals) as the PCL or VES coupling interval decreases. Conversely, nondecremental VA conduction characterizes BT conduction. Nonetheless, some BTs with retrograde decremental conduction properties can also exhibit prolongation of conduction time and VA interval with ventricular pacing or VES. In addition, at short ventricular PCLs or VES coupling intervals, intramyocardial conduction delay can occur, resulting in prolongation in the VA interval; however, the local VA interval at the BT location remains unchanged. Furthermore, short ventricular PCLs or VES coupling intervals can encroach on the BT refractoriness, causing some decremental conduction, with a consequent increase in the surface VA interval and the local VA interval.

The absence of VA conduction (at long ventricular PCLs) or the presence of decremental VA conduction makes the presence of a retrogradely conducting BT unlikely, except for the rare catecholamine-dependent BTs that require isoproterenol infusion for demonstration.

Retrograde atrial activation sequence. In the presence of a retrogradely conducting AV BT (whether manifest or concealed), VES during NSR can result in VA conduction over the BT, AVN, both, or neither (Fig. 18.25). Conduction over the BT alone is the most common pattern at short PCLs or short VES coupling intervals. In this setting, the VA conduction time is fairly constant over a wide range of PCLs and VES coupling intervals (given the absence of intraventricular conduction abnormalities or additional BTs). On the other hand, retrograde conduction over both the BT and HPS-AVN is especially common when RV pacing is performed at long PCLs or long VES coupling intervals and in the presence of a left-sided BT. This occurs because it is easier to engage the RB and conduct retrogradely through the AVN than it is to reach a distant left-sided BT. In this setting, the atrial activation pattern depends on the refractoriness and conduction times over both pathways and usually exhibits a variable degree of fusion. In addition, VA conduction can proceed over the HPS-AVN alone, resulting in a normal pattern of VA conduction, or can be absent because of block in both the HPS-AVN and BT, which is especially common with short PCLs and very early VES.

Ventricular stimulation resulting in eccentric retrograde atrial activation sequence not consistent with normal conduction over the AVN is consistent with VA conduction over an AV BT (see Fig. 18.25). Ventricular pacing can also reveal the presence of multiple BTs (Fig. 18.26). However, a concentric retrograde atrial activation sequence does not exclude the presence of a septal or paraseptal BT or a free-wall BT when VA conduction is mediated by the AVN. In addition, AVN slow pathway conduction can be associated with an eccentric atrial activation sequence in the CS. Accurate analysis of an atrial activation sequence frequently

Fig. 18.25 Retrograde Conduction During Ventricular Extrastimulation (VES) in a Patient With a Bidirectional Left Lateral Bypass Tract (BT). (A) The ventricular pacing drive is conducted retrogradely over the atrioventricular node (AVN) with a concentric atrial activation sequence. The VES is conducted over both the AVN and BT (atrial fusion). (B) An earlier VES encounters delay in the His-Purkinje system (HPS)–AVN and conducts solely over the BT with an eccentric atrial activation sequence. (C) An early-coupled VES blocks retrogradely in the BT and conducts solely over the AVN. (D) The VES conducts only over the HPS-AVN with more pronounced ventriculoatrial (VA) delay, which allows recovery of the BT and anterograde conduction, initiating antidromic atrioventricular reentrant tachycardia (AVRT). The VA delay is provided by conduction delay, not only within the AVN but also within the HPS. Note that the VES encounters retrograde block in the right bundle branch, and His bundle activation is mediated by retrograde conduction over the left bundle branch. Consequently, the His potential is visible after the ventricular electrogram. Note that despite the fact that the H1-H2 interval following VES approximates the H-H interval during supraventricular tachycardia (SVT), the His bundle–atrial interval following the initiating VES is shorter than that during the SVT, which favors antidromic AVRT over preexcited atrioventricular nodal reentrant tachycardia as the mechanism of the SVT. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; HRA, high right atrium; RVA, right ventricular apex.

Fig. 18.26 Ventricular Pacing Revealing the Presence of Multiple Bypass Tracts (BTs). The first complex shows sinus rhythm with preexcitation, showing a left free-wall pattern. Four complexes of right ventricular apical (RVA) pacing follow, the first two paced complexes (S) show fusion of retrograde activation over both a left lateral BT (red arrows), which is present in each complex, and a right lateral BT (blue arrows). The last two paced complexes conduct over the left lateral BT. Dashed lines aid in comparing activation sequences. requires the use of multielectrode catheters around the tricuspid annulus and deep in the CS.²⁷

VES during HB refractoriness. A VES delivered when the HB is refractory (i.e., when the His potential is already manifest or within 35 to 55 milliseconds before the time of the expected His potential) that results in atrial activation is diagnostic of the presence of a retrogradely conducting BT. Because the HPS-AVN is already refractory and cannot mediate VA conduction, retrograde atrial activation from ventricular stimulation has to be mediated by a BT.

Furthermore, an early coupled VES that results in an atrial activation that either precedes HB activation (Fig. 18.27) or is associated with an apparent HA interval shorter than that during drive complexes indicates “atrial preexcitation” via an AV BT.

Importantly, if a VES delivered when the HB is refractory does not result in atrial activation, this does not necessarily exclude the presence of a retrogradely conducting AV BT, because such a VES can be associated with retrograde block in the BT itself (see Fig. 18.25). In addition, the lack of such a response does not exclude the presence of unidirectional (anterograde-only) AV BTs.

Retrograde RBBB during VES. During the delivery of progressively premature single VESs, an abrupt increase in the VA conduction interval is often observed. This can be due to a variety of reasons including: (1) retrograde block in the AVN fast pathway and subsequent VA conduction over the slow pathway; (2) retrograde block in the RB and subsequent retrograde conduction over the left bundle branch (LB); or (3) retrograde block in the BT and subsequent VA conduction only over the AVN.

Fig. 18.27 Ventricular Extrastimulation Revealing the Presence of a Bypass Tract (BT). A retrograde His potential is present on both drive complexes (*S1*) and following the extrastimulus (*arrows*). Although atrial activation also follows each stimulus, it occurs (*dashed line*) before the inscription of the His potential on the ventricular extrastimulus (*S2*). Thus a BT is present because atrial activation is not dependent on His bundle–atrioventricular activation. *CS_{dist}*, Distal coronary sinus; *CS_{mid}*, middle coronary sinus; *CS_{prox}*, proximal coronary sinus; *His_{dist}*, distal His bundle; *His_{mid}*, middle His bundle; *His_{prox}*, proximal His bundle; *HRA*, high right atrium; *RVA*, right ventricular apex.

Retrograde RBBB occurs frequently during VES testing, and can be diagnosed by observing the retrograde His potential during the drive train and its abrupt delay following the VES. Often, however, it is difficult to visualize the retrograde His potential during the pacing train; nevertheless, the sudden appearance of an easily distinguished retrograde His potential, separate from the ventricular electrogram following the VES, can be sufficient to recognize retrograde RBBB.

Prolongation of the ventriculo-His (VH) interval is observed on development of retrograde RBBB because conduction must traverse the interventricular septum (which requires approximately 60 to 70 milliseconds in normal hearts), enter retrograde via the LB, and ascend to reach the HB. Although an increase in the VH interval necessarily occurs with retrograde RBBB, whether a similar increase occurs in the VA interval depends on the nature of VA conduction (over the AVN vs. BT).

Measurement of the effect of the development of retrograde RBBB during VES on the retrograde VH and VA intervals can help distinguish between retrograde AVN and BT conduction. In the absence of a BT, the AVN can be activated in a retrograde fashion only after retrograde activation of the HB; as a consequence, VA activation will necessarily be delayed with retrograde RBBB, and the increase in the VA interval will be similar to the increase in the VH interval. On the other hand, when retrograde conduction is via a BT, there will be no expected increase in the VA interval when retrograde RBBB is induced. Thus the increase in the VA interval is minimal and always less than the increase in the VH interval.²⁸

Differential-site RV pacing. The response of the VA interval (i.e., the stimulus-to-atrial [SA] interval) and atrial activation sequence to differential-site RV pacing (i.e., RV basal versus RV apical pacing) can

help demonstrate or exclude the presence of a retrogradely conducting septal AV BT (Fig. 18.28).

The RV apex, although anatomically more distant from the atrium than the RV base, is nonetheless electrically closer because of the proximity of the distal RB to the pacing site. Consequently, in the absence of a retrogradely conducting septal AV BT, pacing at the RV apex allows entry into the rapidly conducting HPS and results in a shorter VA interval during pacing from the apex than from the base. Pacing from the RV base requires the paced wavefront to travel a longer distance by muscle-to-muscle conduction to reach the RV apex and then propagate retrogradely through the RB and HB. In other words, the VH interval is shorter with pacing at the RV apex versus the RV base. In the presence of a retrogradely conducting septal BT, pacing at the RV base allows the wavefront to access the BT rapidly and activate the atrium with a shorter VA interval than during RV apical pacing, which is distant from the ventricular insertion site of the BT (i.e., because the V-BT interval is shorter with pacing at the RV base versus the RV apex).

In the absence of a retrogradely conducting BT, the atrial activation sequence will be similar during pacing at the RV apex and at the RV base because the atrium is activated exclusively over the AVN in both settings. On the other hand, if a septal AV BT is present, atrial activation results from VA conduction over the septal BT during pacing at the RV base, and over the AVN, the BT, or a fusion of both during pacing at the RV apex. Therefore a change in the retrograde atrial activation sequence in response to RV base versus RV apex pacing indicates the presence of an AV BT, but a constant atrial activation sequence is not helpful in excluding the presence of a BT.

Of note, the exact entrance to the HPS (i.e., the terminus of the RB) is difficult to identify; the entrance site can be located in the

Fig. 18.28 Differential-Site Right Ventricular (RV) Pacing in a Patient With Concealed Superoparaseptal Bypass Tract (BT). In each panel, the first two complexes show RV basal-septal pacing, and the last two complexes show RV apical pacing. (A) RV pacing is performed before ablation of the BT. The stimulus-to-atrial (SA) (ventriculoatrial [VA]) interval is shorter during pacing at the RV base than during pacing at the RV apex, suggesting VA conduction occurring over a BT. Note that atrial activation occurs even before His bundle (HB) activation during pacing from the RV base, suggesting that VA conduction is independent of the atrioventricular node (AVN). (B) RV pacing is performed after successful ablation of the BT. During pacing from the RV apex, the SA interval is longer than before ablation, and it prolongs further by pacing at the RV base, consistent with the occurrence of VA conduction exclusively over the AVN. Note that in both panels the stimulus–His bundle (SH) (ventriculo-His) interval during RV apical pacing is shorter than that during RV basilar pacing because of the faster access of the paced wavefront to the right bundle branch–His bundle (RB–HB) during pacing at the RV apex. However, when VA conduction occurs over a BT (A), the SA interval remains constant; in contrast, in the absence of a BT (B), the SA interval shortens, coinciding with shortening of the S–H interval during pacing at the RV apex compared with pacing at the RV base. *CS_{dist}*, Distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *HRA*, high right atrium; *RVA*, right ventricular apex.

Fig. 18.30 Para-Hisian Pacing in a Patient With a Concealed Superoparaseptal Bypass Tract (BT). In each panel, the first two complexes show right ventricle (RV)-only capture, and the last two complexes show RV and His bundle–right bundle branch (HB-RB) capture. The loss of HB-RB capture is identified by delay in the HB activation (stimulus–His bundle [SH] interval = 60 milliseconds) and widening of the QRS. The His potential is not visible during HB-RB capture. (A) Para-Hisian pacing is performed before ablation of the BT; the stimulus-atrial (SA) interval remains unchanged regardless of whether HB-RB capture occurs, because retrograde ventriculoatrial (VA) conduction occurs over the BT in either setting. In fact, during RV-only capture, the SA interval is shorter than the SH interval, indicating that VA conduction is independent of the atrioventricular node (AVN). (B) Para-Hisian pacing is performed after successful ablation of the BT; the SA interval is longer than before ablation, and it prolongs further on loss of HB-RB capture, concomitant with delay in HB activation (i.e., prolongation in the SH interval) and a constant HA interval, indicating that VA conduction is mediated only by the AVN. Note that the activation sequence before ablation (VA conduction occurring over the BT) is slightly different from after ablation (VA conduction occurring over the AVN). However, in each case (preablation and postablation), the atrial activation sequence occurs over the same pathway and remains constant, regardless of whether HB-RB occurs. *CS_{dist}*, Distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *His_{dist}*, distal His bundle; *His_{prox}*, proximal His bundle; *HRA*, high right atrium; *RVA*, right ventricular apex.

whereas prolongation of the VA (SA) interval on loss of HB capture, compared with that during HB capture, excludes the presence of a retrogradely conducting septal BT, except for slowly conducting and far free-wall BTs.³¹

Dual-Chamber Sequential Extrastimulation During Sinus Rhythm

Although the various ventricular pacing maneuvers described previously can expose an eccentric or nondecremental atrial activation pattern that suggests retrograde conduction over a BT rather than the AVN, in certain circumstances, these maneuvers may not be adequate to confirm the presence or absence of BT conduction, especially when the BT has an ERP, retrograde atrial activation pattern, and conduction time similar to the AVN. In particular, identification, mapping, and verification of success of ablation of BT function can be challenging in the setting of septal BTs with a retrograde activation pattern similar to retrograde AVN conduction, slowly conducting BTs, as well as BTs with decremental properties.³²

Dual-chamber sequential extrastimulation is a useful maneuver for identifying concealed slowly conducting BTs not revealed with standard pacing maneuvers. This maneuver relies on concealed AVN conduction during a critically timed AES to cause transient retrograde AVN blockade at the time a VES is delivered, thereby allowing the BT to become manifest with the VES (analogous to delivering a VES during SVT while the HB is refractory).³²

The dual-chamber sequential extrastimulation maneuver consists of an eight-beat drive train of simultaneous atrial and RV pacing at 600 milliseconds, followed by an AES (A2) delivered at a coupling interval equal to the AVN ERP, followed by a VES (V2) delivered at a coupling interval equal to the drive train CL (600 milliseconds). Repeat drives are then performed with decrements of 10 milliseconds for V2 until VA block is observed.³²

The critically timed A2 prolongs the AVN refractory period via concealed anterograde conduction, causing V2 to block in the AVN when it would have conducted had A2 not been delivered. If a BT is

present, V2 conducts back to the atrium while the AVN remains refractory, resulting in a retrograde atrial activation pattern consistent with exclusive BT conduction. Although there can also be some degree of concealed anterograde conduction into the BT during A2 stimulation, the more pronounced decremental properties of AVN tissue should prolong AVN refractoriness to a greater degree than that of the BT, allowing exclusive retrograde conduction over the BT to remain intact during V2 stimulation.³²

This maneuver has several potential limitations. First, atrial ERP may exceed anterograde AVN ERP. In addition, local atrial ERP at the site of BT insertion can render the atrium refractory to the wavefront traveling retrogradely over the BT. Therefore atrial pacing during this maneuver should ideally be performed at a site in close proximity to the atrial insertion of the BT if possible. Furthermore, the AES may cause anterograde concealed conduction in the BT, potentially resulting in BT conduction block during delivery of V2. The success of this pacing maneuver relies on the differential effects of concealed conduction into the AVN and BT, with greater extension of refractoriness in the former than the latter.³²

Induction of Tachycardia

Initiation by Programmed Atrial Stimulation

Orthodromic AVRT: bidirectional AVT BT. In the presence of a manifest AV BT, initiation of orthodromic AVRT with an AES requires the following: (1) anterograde block in the AV BT; (2) anterograde conduction over the AVN-HPS; and (3) slow conduction over the AVN-HPS, with adequate delay to allow for the recovery of the atrium and AV BT and subsequent retrograde conduction over the BT (Fig. 18.31; see Fig. 3.9). The first two requirements are facilitated by the fact that, while the BT conducts more rapidly than the AVN, it has a longer ERP, so the early atrial impulse blocks anterogradely in the BT but conducts over the AVN. For the third condition, the site of AV delay is not important; it is most commonly in the AVN, but it can also occur in the HB, bundle branches, or ventricular myocardium. Because the coupling intervals of the AES required to achieve anterograde block in

Fig. 18.31 Induction of an Orthodromic Atrioventricular Reentrant Tachycardia (AVRT) Using a Bidirectional Bypass Tract (BT) With Atrial Pacing. Rapid atrial pacing is initially associated with ventricular preexcitation via a left lateral BT. With pacing at a progressively shorter cycle length, anterograde block in the BT develops, as evident with loss ventricular preexcitation concurrent with prolongation of the PR interval. Cessation of pacing is followed by initiation of orthodromic AVRT utilizing the same BT as the retrograde limb of the reentry circuit. CS_{dist}, distal coronary sinus; CS_{prox}, proximal coronary sinus; HRA, high right atrium; RVA, right ventricular apex.

the BT are usually short, sufficient AVN delay is usually present so that orthodromic AVRT is initiated once anterograde BT block occurs. The presence of dual AVN physiology can facilitate the initiation of orthodromic AVRT by providing adequate AV delay by mediating anterograde conduction over the slow AVN pathway. BBB ipsilateral to the AV BT provides an additional AV delay that can facilitate tachycardia initiation.

Induction of orthodromic AVRT is easier with atrial stimulation at a site in close proximity to the AV BT insertion site; the closer the stimulation site is to the BT, the easier it is to encroach on the refractory period of the BT and achieve block, because it is not limited by the refractoriness or conduction time of intervening atrial tissue. Furthermore, the earlier the atrial insertion of the BT is activated, the more likely it will recover before arrival of the retrograde wavefront to the BT atrial insertion site, thereby facilitating reentry. Thus one may actually require less anterograde AV delay if recovery of excitability is shifted earlier in time. In addition, different sites of atrial stimulation can produce different AVN conduction velocities and refractoriness (even at the same AES coupling intervals).

If SVT induction fails, the use of multiple AESs, rapid atrial pacing, and pacing closer to the BT would achieve block in the BT and produce adequate AV delay.

AES can also result in a 1:2 response caused by conduction over both the BT and the AVN-HPS (i.e., a single AES resulting in two ventricular complexes; the first is fully preexcited and the second is normal). For this response to occur, significant delay in AVN-HPS conduction should be present (usually anterograde conduction is mediated by the slow AVN pathway) to allow for recovery of the ventricle after its activation via the BT. AES can also produce sinus nodal or AVN echo beats that in turn may block in the BT and achieve adequate AV delay to initiate orthodromic AVRT.

Orthodromic AVRT: concealed AV BT. Orthodromic AVRT in patients with concealed BTs is identical to that in patients with manifest BTs (Figs. 18.32 and 18.33). The only difference is that in patients with concealed BTs, anterograde block in the BT is already present. Consequently, the only condition needed to induce orthodromic AVRT is adequate AV delay (in the AVN or HPS) to allow for recovery of the atrium and atrial insertion site of the AV BT. Therefore orthodromic AVRT initiation requires less premature coupling intervals of the AESs in patients with concealed BTs than in patients with WPW.

Permanent junctional reciprocating tachycardia. PJRT is usually incessant and is initiated by spontaneous shortening of the sinus CL, without a triggering PAC or PVC. The tachycardia can be transiently terminated by PACs or PVCs but usually resumes after a few sinus beats (eFig. 18.5). This phenomenon has three potential mechanisms: a rate-related decrease in the retrograde ERP of the BT, a rate-related decrease in atrial refractoriness that allows the impulse to reactivate the atrium retrogradely over the BT, or a concealed Wenckebach block with block at the atrial-BT junction terminating the Wenckebach cycle, relieving any anterograde concealed conduction that may have prevented retrograde conduction up the BT. The latter is the most likely mechanism, because such slow BTs actually demonstrate decremental conduction at rapid rates and, in most cases, the atrial ERP at the atrial-BT junction is shorter than the RP (VA) interval. Thus some sort of anterograde concealment during NSR in the BT must be operative, preventing tachycardia from always occurring. Late-coupled AESs can also readily initiate PJRT.

Antidromic AVRT. The initiation of antidromic AVRT by an AES requires the following: (1) intact anterograde conduction over the BT; (2) anterograde block in the AVN or HPS; and (3) intact retrograde conduction over the HPS-AVN once the AVN resumes excitability

Fig. 18.32 Induction of an Orthodromic Atrioventricular Reentrant Tachycardia Using a Concealed Bypass Tract (BT) With Atrial Extrastimulation (AES). Note that the AES (S2) conducts with atrioventricular (AV) delay, which allows for recovery of the atrium and atrial insertion site of the AV BT. The atrial activation sequence during the tachycardia is eccentric in the coronary sinus recording, consistent with left free lateral BT. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; HRA, high right atrium; RVA, right ventricular apex.

eFig. 18.5 Permanent Junctional Reciprocating Tachycardia (PJRT). Two surface electrocardiogram leads are shown during PJRT. Carotid sinus pressure is applied (*at left*), resulting in termination of the tachycardia caused by block in the bypass tract (the tachycardia terminates with a QRS). Several escape and sinus complexes follow, and then the SVT resumes. This phenomenon gives rise to the use of the term *permanent* or *incessant*.

Fig. 18.33 Induction of an Orthodromic Atrioventricular Reentrant Tachycardia (AVRT) Using a Concealed Bypass Tract (BT) With Atrial Pacing. The last atrial paced complex conducts anterogradely over the slow atrioventricular nodal (AVN) pathway and results in an AVN echo beat (blue arrow and shade) and simultaneous atrial and ventricular activation. The echo beat induces orthodromic AVRT with an eccentric atrial activation sequence (red arrow and shade), consistent with left free lateral BT. Note that the VA interval during the AVN echo beat is significantly shorter than that during orthodromic atrioventricular nodal reentrant tachycardia. CS_{dist} , Distal coronary sinus; CS_{prox} , proximal coronary sinus; HRA, high right atrium; RVA, right ventricular apex.

following partial anterograde penetration (see Fig. 18.23). The latter is usually the limiting factor for the initiation of antidromic AVRT. A delay of more than 150 milliseconds between atrial insertion of the BT and HB is probably required for the initiation of antidromic AVRT.

Several mechanisms of antidromic AVRT initiation can be operative. The AES can block in the AVN with anterograde conduction down the BT and subsequent retrograde conduction over the HPS-AVN. In this setting, VH interval prolongation is required to allow recovery of the AVN. Because antidromic AVRTs have relatively short VA intervals, this mechanism of initiation is probably uncommon, except with left-sided BTs, which would potentially provide sufficient VH delay to allow retrograde conduction. Tachycardia initiation can be facilitated by a short retrograde AVN ERP, a common finding in patients with these SVTs. Alternatively, the AES may block in the AVN, with anterograde conduction down the BT and subsequent retrograde conduction over a different BT. Subsequent complexes can conduct retrogradely over the AVN-HPS or the second BT. Changing TCL (and VA interval) may relate to whether retrograde conduction proceeds over the AVN-HPS or the second BT. A third potential mechanism for the initiation of antidromic AVRT involves AES conduction over the BT and simultaneously over the slow pathway of a dual AVN pathway situation, with anterograde block in the fast AVN pathway. Conduction beyond the HB to the ventricle is not possible because of ventricular refractoriness, yet an AVN echo to the atrium may occur, which in turn may conduct anterogradely over the BT, when the ventricle would have recovered excitability, and subsequently back up the now-recovered AVN, initiating antidromic AVRT. AVN reentry may not persist or may be preempted by retrograde con-

duction up the fast AVN pathway because of the premature ventricular activation over the BT. In this scenario, the location of the His potential will depend on whether it was anterograde or retrograde.

In general, if atrial stimulation induces antidromic AVRT, multiple BTs are often operative. Whether they are operative throughout the SVT depends on the relative retrograde activation times over the additional BTs and HPS-AVN and the varying degree of anterograde and retrograde concealment into the additional BTs and HPS-AVN during the SVT.

The site of atrial stimulation plays an important role in inducibility of AVRT, and can also determine the type of AVRT initiated in patients with bidirectional BTs. The closer the stimulation site to the BT, the more likely anterograde block in the BT will occur and orthodromic AVRT will result. Conversely, antidromic AVRT is more likely to occur with atrial stimulation close to the AVN.

Initiation by Programmed Ventricular Stimulation

Orthodromic AVRT. Ventricular stimulation can induce orthodromic AVRT in the majority of patients (inducibility rate of 60% with VES and 80% with ventricular pacing), regardless of whether the BT is manifest or concealed (Fig. 18.34). Initiation of orthodromic AVRT by ventricular stimulation requires the following: (1) retrograde block of the ventricular impulse in the HPS-AVN; (2) retrograde conduction only over the BT; and (3) adequate VA conduction delay to allow for recovery of the AVN-HPS from any concealment produced by ventricular stimulation, so it can support anterograde conduction of the reentrant impulse. Because the BT retrograde ERP is usually very short, the prime

Fig. 18.34 Induction of an Orthodromic Atrioventricular Reentrant Tachycardia (AVRT) Using a Concealed Posteroseptal Bypass Tract With Ventricular Pacing. Note that although the ventricular pacing cycle length (CL) approximates the tachycardia CL, the ventriculoatrial (VA) interval (*dashed lines*) during ventricular pacing is only slightly longer than that during supraventricular tachycardia (SVT), which favors orthodromic AVRT over atrioventricular nodal reentrant tachycardia as the mechanism of the SVT. In addition, the atrial–His bundle interval of the first SVT complex is longer than that of subsequent beats, indicating retrograde concealment in the AVN produced by the last ventricular stimulus. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; HRA, high right atrium; RVA, right ventricular apex.

determinant of orthodromic AVRT initiation is the extent of retrograde conduction and/or concealment in the HPS-AVN.

Multiple modes of initiation of orthodromic AVRT can be present, depending on the PCL or VES coupling interval, conduction velocities, and refractoriness of the HPS-AVN and BT, as well as the site of ventricular stimulation. Ventricular pacing at a CL or a VES with a coupling interval that is shorter than the ERP of the AVN but longer than that of the HPS and BT would block retrogradely in the AVN and conduct over the BT to initiate orthodromic AVRT. Block in the AVN, which is more likely to occur with rapid ventricular pacing or VES delivered after a short pacing drive CL, can cause concealment and subsequent delay in anterograde conduction of the first SVT impulse over the AVN, resulting in longer AH and PR intervals of the first SVT beat compared with subsequent beats (see Fig. 18.34). On the other hand, ventricular pacing at a CL or a VES with a coupling interval shorter than the ERP of the HPS, but longer than that of the BT, would block retrogradely in the HPS and conduct over the AV BT to initiate orthodromic AVRT. When block occurs in the HPS, which is more likely to occur with a VES delivered during NSR or after a long pacing drive CL, the first SVT beat will approach a fully recovered AVN and conduct with short AH and PR intervals equal to subsequent SVT beats. In this setting, adequate prolongation of the HV interval may be required to allow for the recovery of ventricular refractoriness for the ventricle to be activated and support reentry, because AVN delay may have not been sufficient. When HV interval prolongation is required to initiate orthodromic AVRT, it is almost invariably associated with LBBB. A short-coupled VES, especially following a pacing drive with a long CL, that blocks retrogradely in both the BT and RB and conducts transseptally and then retrogradely over the LB, can result in a bundle branch reentrant (BBR) beat that conducts to the ventricle down the RB, and then retrogradely to the atrium over the AV BT, mediating the initiation of orthodromic AVRT. The long HV interval often associated with BBR beats, plus the LBBB pattern, facilitate the induction of orthodromic AVRT using a left-sided BT (Fig. 18.35).

When induction of the SVT is achieved by ventricular pacing at a PCL similar to the subsequent TCL or by a VES that activates the HB

at a coupling interval (i.e., H1-H2 interval) similar to the H-H interval during the SVT (i.e., similar to the TCL), the HA interval following the initiating ventricular stimulus is then compared with that during the SVT. During AVNRT, the HA interval of the ventricular stimulus initiating the SVT is longer than the HA interval during the SVT because both the HB and atrium are activated in sequence during ventricular stimulation but in parallel during AVNRT (see Fig. 17.14). This is even exaggerated by the fact that the AVN usually exhibits greater decremental conduction with repetitive engagement of impulses than to a single impulse at a similar coupling interval. Therefore the more prolonged the HA interval with the initiating ventricular stimulus, the more likely the SVT is AVNRT. On the other hand, if the SVT uses an AV BT for retrograde conduction, the HA interval during the initiating ventricular stimulus (at a coupling interval comparable to the TCL) is shorter than that during orthodromic AVRT because the HB and atrium are activated in parallel during ventricular pacing (when atrial activation is mediated by retrograde BT conduction), but in sequence during SVT.

The intervals immediately following tachycardia initiation with a VES (delivered from the RV apex) provide data that are essentially equivalent to those observed with ventricular entrainment (see later). The interval from the VES to atrial activation (surface VA or “SA” interval) is compared to the surface VA interval during SVT, and the post-VES return cycle (i.e., the interval from the VES to the subsequent RV apical depolarization) is compared to the TCL. An SA interval that exceeds the surface VA interval during SVT by less than 85 milliseconds is consistent with orthodromic AVRT. Similarly, when the post-VES return cycle exceeds the TCL by less than 115 milliseconds, orthodromic AVRT is suggested. The small differences between those intervals are related to the proximity of the RV apical pacing site to the SVT reentry circuit. Larger differences in these intervals are observed in the setting of AVNRT or orthodromic AVRT utilizing a left lateral BT or a septal BT with decremental conduction. The unique advantage of this technique is that it does not require a sustained tachycardia that can be successfully entrained.³³

Permanent junctional reciprocating tachycardia. Ventricular stimulation is less effective in initiating PJRT because of the already

Fig. 18.35 Induction of an Orthodromic Atrioventricular Reentrant Tachycardia (AVRT) Using a Concealed Left Posteroseptal Bypass Tract (BT) With Ventricular Extrastimulation (VES). The VES conducts retrogradely over the BT, but also results in a bundle branch reentrant (BBR) beat, which in turn conducts to the atrium over the BT and initiates orthodromic AVRT. Note that right bundle branch block (RBBB) develops shortly after initiation of the tachycardia; however, the ventriculoatrial (VA) interval (dashed lines) remains constant, regardless of the presence or absence of RBBB, because the BT is in the contralateral ventricle. *CS_{dist}*, Distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *HRA*, high right atrium; *RVA*, right ventricular apex.

impaired conduction in the BT, such that an early VES produces block in the BT. A late-coupled VES (when the HB is refractory) can initiate SVT in some cases.

Antidromic AVRT. Initiation of classic antidromic AVRT by ventricular pacing and VES requires the following: (1) retrograde block in the BT; (2) retrograde conduction over the AVN or HPS; and (3) adequate VA delay to allow for recovery of the atrium and BT so it can support subsequent anterograde conduction (see Fig. 18.25).

When induction of the SVT is achieved by ventricular pacing at a CL similar to the TCL or by a VES that activates the HB at a coupling interval (i.e., H1-H2 interval) similar to the H-H interval during the SVT, the HA interval following the initiating ventricular stimulus is always equal to or shorter than that during the antidromic AVRT. This is because the HB and atrium are activated in sequence during antidromic AVRT and in parallel during ventricular stimulation (in the presence of a retrogradely conducting BT). Therefore an HA interval of the initiating ventricular stimulus longer than the HA interval during SVT favors preexcited AVNRT and excludes antidromic AVRT (see Fig. 18.25). Moreover, because the AVN usually exhibits greater decremental conduction with repetitive engagement of impulses than to a single impulse at a similar coupling interval, the more prolonged the HA interval with the initiating ventricular stimulus, the more likely that the SVT is preexcited AVNRT.

Tachycardia Features

Orthodromic Atrioventricular Reentrant Tachycardia

Atrial activation sequence. The initial site of atrial activation during orthodromic AVRT depends on the atrial insertion site of the BT, but is always near the AV groove and without multiple breakthrough points. The atrial activation sequence during orthodromic AVRT should be identical to that during ventricular pacing at comparable CLs when VA conduction occurs exclusively over the BT. However, retrograde conduction during ventricular pacing can proceed over the AVN or over both the BT and AVN, resulting in fusion of atrial activation, depending on the site of ventricular stimulation relative to the BT and HPS, and on retrograde conduction and refractoriness of the HPS-AVN.

Atrial-ventricular relationship. The conduction time over the typical (fast) AV BT is approximately 30 to 120 milliseconds. Therefore the RP interval during orthodromic AVRT is short, but longer than that during typical AVNRT, because in the setting of orthodromic AVRT the wavefront has to activate the ventricle before it reaches the ventricular insertion site of the BT at the AV groove and subsequently conduct to the atrium. Consequently, a very short VA interval (less than 70 milliseconds) or short V–high RA interval (less than 95 milliseconds) largely excludes orthodromic AVRT, and favors typical AVNRT (see Fig. 18.33).³⁴ However, VA intervals shorter than 70 milliseconds have occasionally been observed in patients with orthodromic AVRT utilizing left lateral or left posteroseptal BTs.³⁵ Importantly, the RP and VA intervals during orthodromic AVRT remain constant regardless of oscillations in the TCL from whatever cause and regardless of changes in the PR interval (AH interval); as a consequence, the TCL is most closely associated with the PR interval (i.e., anterograde AVN conduction) and the RP/PR ratio may vary (Fig. 18.36).

A 1:1 A-V relationship is a prerequisite for maintenance of AVRT because parts of both the atrium and the ventricle are essential components of the reentrant circuit. If an SVT persists despite the presence of AV or VA block, orthodromic AVRT is excluded.

When dual AVN pathways are present, the slow AVN pathway functions in most cases as the anterograde limb during orthodromic AVRT. An AH interval of more than 180 milliseconds during orthodromic AVRT suggests a slow AVN pathway mediating the anterograde limb of the reentrant circuit, whereas an AH interval of less than 160 milliseconds suggests anterograde conduction over the fast AVN pathway. Obviously, orthodromic AVRT using the slow pathway will have a longer TCL.

Slow-slow AVNRT is associated with an RP interval and P wave morphology similar to that during orthodromic AVRT using a posteroseptal AV BT. However, although both SVTs have the earliest atrial activation in the posteroseptal region, conduction time from that site to the HB region is significantly longer in AVNRT than in orthodromic AVRT, resulting in a significantly longer RP interval in lead V1 and a larger difference in the RP interval between lead V1 and the inferior leads. Therefore a Δ RP interval (V1 to III) longer than 20 milliseconds

Fig. 18.36 Spontaneous Termination of Orthodromic Atrioventricular Reentrant Tachycardia (AVRT) Using a Concealed Superoparaseptal Bypass Tract. Note that the tachycardia terminates with an atrial complex not followed by a QRS, consistent with anterograde block in the atrioventricular node (AVN). Also, note the oscillation in the tachycardia cycle length (CL) preceding termination. Changes in H-H and V-V intervals precede the subsequent changes in A-A intervals, and the ventriculoatrial (VA) interval remains constant despite oscillation of the CL. This indicates that the variability in the tachycardia CL is secondary to changes in the anterograde conduction over the AVN, whereas VA conduction over the retrograde limb of the reentrant circuit (the bypass tract) remains constant. CS_{dist} , Distal coronary sinus; CS_{prox} , proximal coronary sinus; HRA, high right atrium; RVA, right ventricular apex.

suggests slow-slow AVNRT with a sensitivity of 71%, specificity of 87%, and positive predictive value of 75%.

Effects of BBB. The presence of BBB during SVT is much more common in orthodromic AVRT than AVNRT or AT; in fact, the majority of SVTs with sustained LBBB are orthodromic AVRTs. Two reasons have been proposed to explain why prolonged aberration occurs less commonly during AVNRT than orthodromic AVRT. First, the induction of AVNRT requires significant AVN delay, which makes the H1-H2 interval longer and makes aberration unlikely. Conversely, in orthodromic AVRT, AVN conduction need not be slow, resulting in a shorter AH interval and an impulse encroaching on HPS refractoriness, in turn resulting in BBB. Second, LBBB facilitates the induction of orthodromic AVRT when a left-sided AV BT is present by providing the necessary AV delay required to maintain the reentry circuit.³⁶

BBB is more common when AVRT is initiated by an AES that is delivered during NSR or after long pacing drive CLs, during which HPS refractoriness is longest and AVN conduction and refractoriness are shortest. When AVRT is induced by atrial stimulation, RBBB is twice as common as LBBB. In contrast, when AVRT is induced by ventricular stimulation, LBBB is much more common than RBBB (because of retrograde concealment of the paced wavefront in the LB). In addition, the incidence of BBB is more common in AVRTs induced by ventricular stimulation than those induced by atrial stimulation (75% vs. 50%).

BBB ipsilateral to the BT results in prolongation of the “surface VA interval.” Block in the ipsilateral bundle branch forces the reentrant circuit to follow a longer path. Hence, more time is needed for the tachycardia wavefront to travel from the AVN down the HB and contralateral bundle branch, and then transseptally to the ventricle ipsilateral to the BBB in order to reach the BT and then activate the atrium

(Fig. 18.37). However, the “local VA interval” (measured at the site of BT insertion) remains constant. On the other hand, the TCL usually increases in concordance with the increase in the surface VA interval as a result of ipsilateral BBB because of the now larger tachycardia circuit. However, because the time the wavefront spends outside the AVN is now longer because of the larger circuit, AVN conduction may improve to a small degree, resulting in shortening of the AH interval (PR interval), which can potentially counterbalance, at least in part, the effects of prolongation of the VA interval on the total TCL. Thus the surface VA interval and not the TCL should be used to assess the effects of BBB on the SVT (see Figs. 18.37 and 18.38).

Prolongation of the surface VA interval during SVT in response to BBB by more than 35 milliseconds compared to that with normal QRS or contralateral BBB indicates that an ipsilateral free-wall BT is present and is participating in the SVT (i.e., diagnostic of orthodromic AVRT) (see Fig. 18.38). On the other hand, prolongation of the surface VA by 25 to 35 milliseconds suggests a septal or paraseptal BT (posteroseptal AV BT in association with LBBB, and superoparaseptal AV BT in association with RBBB). In contrast, BBB contralateral to the BT does not influence the VA interval or TCL because the contralateral ventricle is not part of the reentrant circuit (see Figs. 18.35 and 18.37). Of note, prolongation of the VA interval by more than 45 milliseconds in response to RV pacing entraining the orthodromic AVRT is also diagnostic of a left-sided BT, whereby RV pacing results in effects analogous to those created by LBBB and, as a consequence, VA interval prolongation.

Oscillations in the tachycardia cycle length. Oscillation of the TCL during orthodromic AVRT can occur and generally is caused by changes in the anterograde conduction over the AVN (see Fig. 18.36). Because retrograde conduction through the BT is much less variable,

Fig. 18.37 Schematic Illustration of the Effect of Bundle Branch Block on the Reentrant Circuit During Orthodromic Atrioventricular Reentrant Tachycardia (AVRT) Using a Left-Sided Bypass Tract (BT). Block in the left bundle branch (LB) (ipsilateral to the BT) results in prolongation of the reentrant pathway and, therefore, prolongation of the ventriculoatrial interval. In contrast, block in the right bundle branch (RB) (contralateral to the BT) has no effect on the reentrant circuit. AVN, Atrioventricular node; HB, His bundle; LBBB, left bundle branch block; RBBB, right bundle branch block.

Fig. 18.38 Effect of Bundle Branch Block on Orthodromic Atrioventricular Reentrant Tachycardia (AVRT). Orthodromic AVRT is recorded in the same patient. (A) Orthodromic AVRT with normal intraventricular conduction. (B) Orthodromic AVRT with right bundle branch block (RBBB). (C) Orthodromic AVRT with left bundle branch block (LBBB). Note that the tachycardia cycle length (TCL) and ventriculoatrial (VA) interval are not affected by the development of RBBB. In contrast, the development of LBBB during tachycardia is associated with prolongation of the VA interval (by 38 milliseconds) and a lesser degree of prolongation of the TCL (by 25 milliseconds), indicating the presence and participation of a left lateral bypass tract in the reentrant circuit. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; His_{dist}, distal His bundle; His_{mid}, middle His bundle; His_{prox}, proximal His bundle; HRA, high right atrium; RVA, right ventricular apex.

the changes in ventricular CL that result from variability in the antero-grade AVN conduction precede the subsequent changes in atrial CL, and changes in atrial CL do not predict changes in subsequent ventricular CL (similar to observations during typical AVNRT). In contrast, changes in atrial CL predict the changes in subsequent ventricular CL during atypical AVNRT and AT.³⁷

In addition, orthodromic AVRT in the presence of dual AVN physiology can be associated with antegrade conduction alternating over the slow and fast AVN pathways, resulting in a regular irregularity of the TCL (alternating long and short cycles). Alternatively, the presence of dual AVN pathways can lead to two separate stable TCLs. In either setting, the RP interval during the SVT remains constant.

QRS alternans. Alternans of the QRS complex amplitude during a relatively slow SVT is almost always indicative of orthodromic AVRT (see Fig. 18.13). On the other hand, although QRS alternans during fast SVTs is most commonly seen in orthodromic AVRT, it can also be seen with other types of SVT.

Termination and response to physiological and pharmacological maneuvers. Spontaneous termination of orthodromic AVRT is usually caused by gradual slowing and then block in the AVN (see Fig. 18.36), sometimes causing initial oscillation in the TCL, with alternate com-

plexes demonstrating a Wenckebach periodicity before block. However, termination with block in the BT without any perturbations of the TCL can occur during very rapid AVRT or following a sudden shortening of the TCL (e.g., after resolution of ipsilateral BBB or shift of antero-grade conduction from the slow to the fast AVN pathway).

Carotid sinus massage can terminate orthodromic AVRT by gradual slowing and then block in the AVN. Adenosine, digoxin, verapamil, diltiazem, and beta-blockers terminate orthodromic AVRT by block in the AVN; therefore the SVT terminates with a P wave that is not followed by a QRS. Verapamil rarely produces block in the BT and, when it does, block is usually preceded by oscillation in the TCL produced by changes in AVN conduction, leading to long-short sequences. Class IA and IC antiarrhythmic agents can produce block in the BT with variable effect on the AVN-HPS. Amiodarone can terminate AVRT by block in the AVN, HPS, or AV BT. Sotalol affects the AVN with little or no effect on the AV BT.

Permanent junctional reciprocating tachycardia

Atrial activation sequence. The initial site of atrial activation is most often in the posteroseptal part of the triangle of Koch near the coronary sinus ostium (CS os), similar to that in atypical AVNRT (Fig. 18.39).³

Fig. 18.39 Ventricular Extrastimulation (VES) During Permanent Junctional Reciprocating Tachycardia. The supraventricular tachycardia has a stable baseline cycle length (522 milliseconds). A single VES (*S2*) introduced during His bundle refractoriness retards the timing of the next atrial complex (538 milliseconds). The anticipated timing of the high right atrium electrogram is indicated by the dashed line. *CS_{dist}*, Distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *HRA*, high right atrium; *RVA*, right ventricular apex.

Atrial-ventricular relationship. Because the retrograde limb of the reentry circuit is the slow BT (which conducts more slowly than the AVN), the RP interval is longer than the PR interval, similar to fast-slow AVNRT (see Figs. 18.14 and 18.39). In contrast to the typical (fast) AV BTs, the RP interval during PJRT is not fixed because the BT serving as the retrograde limb of the reentrant circuit has decremental properties. Similar to all types of AVRTs, a 1:1 A-V relationship is a prerequisite to sustenance of the tachycardia.

Oscillations in the TCL. The tachycardia rate typically fluctuates (100 to 220 beats/min) in response to autonomic tone and physical activity, and the rate changes result from modulation of the PR and RP intervals. Typically, the TCL is often just longer than the shortest CL at which the BT can conduct retrogradely.

Effects of BBB. BBB affects PJRT in a manner analogous to that described for orthodromic AVRT.

Termination and response to physiological and pharmacological maneuvers. Carotid sinus massage and AVN blockers (adenosine, digoxin, calcium channel blockers, and beta-blockers) usually terminate PJRT by block in the AVN (two-thirds) or in the BT (one-third) (see eFig. 18.5). Although the mode of tachycardia termination by adenosine has been suggested to distinguish between PJRT and atypical AVNRT, one report has shown that termination of atypical AVNRT with adenosine can also result from block in the fast AVN pathway and, therefore, its value in distinguishing between atypical AVNRT and PJRT is questionable.

Antidromic AVRT

Atrial activation sequence. The initial site of atrial activation in classic antidromic AVRT is consistent with retrograde conduction over the AVN. If the preexcited AVRT is using a second BT for retrograde conduction, then the atrial activation sequence will depend on the location of that BT (see eFig. 18.1). In addition, ventricular activation precedes HB activation by more than 10 milliseconds during classic antidromic AVRT because the ventricle and HB are activated sequentially by the same reentrant wavefront. On the other hand, during preexcited AVNRT, the ventricle and HB can be activated in parallel (the ventricle is activated via the bystander BT and the HB activated via the AVN). Therefore, during a preexcited SVT, a positive HV interval (i.e., HB activation preceding ventricular activation) or

a VH interval not more than 10 milliseconds, especially when the HA interval is not more than 50 milliseconds, favors preexcited AVNRT over antidromic AVRT.

Atrial-ventricular relationship. The conduction time over classic (fast) AV BTs is approximately 30 to 120 milliseconds. Therefore the PR is short and fixed, regardless of oscillations in the TCL from whatever cause. Similar to all types of AVRT, the A/V ratio is always equal to 1. If the SVT persists in the presence of AV or VA block, antidromic AVRT is excluded.

Oscillations in the TCL. Antidromic AVRT can be irregular. Tachycardia CL changes are usually caused by changes in retrograde conduction over different fascicles of the HPS with different VA intervals (regardless of the type and degree of changes in the VH or HA intervals), retrograde conduction over dual AVN pathways (with different HA intervals), different routes of anterograde conduction (with different AV intervals), and/or retrograde conduction over different BTs (with different VA intervals). When the change in the TCL can be ascribed to a change in the VH interval or the subsequent HA interval, it suggests that retrograde conduction occurs over the HPS and AVN and not over a second BT.

The TCL tends to be shorter during classic antidromic AVRT than orthodromic AVRT when these arrhythmias occur in the same patient. This may be explained by the fact that antidromic AVRT uses the fast AVN pathway (of a dual AVN physiology) retrogradely, whereas orthodromic AVRT uses the slow pathway anterogradely or, in the absence of dual AVN physiology, this may be merely supportive evidence that retrograde conduction during antidromic AVRT uses another fast BT instead of the slower AVN. On the other hand, antidromic AVRTs using two or more BTs may have longer TCLs than orthodromic AVRT or classic antidromic AVRT because the two BTs are typically in opposite chambers and are incorporated in a larger reentrant circuit than one involving a midline AVN.

Effects of BBB. Retrograde BBB affects antidromic AVRT in a manner analogous to that described for orthodromic AVRT. Abrupt prolongation of the VH and VA intervals and TCL when retrograde BBB occurs is consistent with retrograde HB activation via the ipsilateral bundle branch, which is typical for antidromic AVRT using an ipsilateral AV BT, but can also occur in preexcited AVNRT. However, if VH

prolongation is accompanied by prolongation of the VA interval (without a change in the activation sequence) and the TCL, true antidromic tachycardia (using the AV conduction system as the retrograde limb) can be diagnosed and preexcited AVNRT is excluded. Lack of effects on the VH interval can occur in: (1) preexcited AVRT (utilizing a second BT as the retrograde limb); (2) antidromic AVRT utilizing a left-sided BT; (3) antidromic AVNRT utilizing an atriofascicular BT inserting into the RB proximal to the site of RBBB; and (4) preexcited AVNRT.

Termination and response to physiological and pharmacological maneuvers. Various physiological and pharmacological maneuvers affect the BT and AVN during antidromic AVRT in a fashion similar to that described for orthodromic AVRT. Carotid sinus massage and adenosine terminate classic antidromic AVRT after ventricular activation, secondary to retrograde block up the AVN. In contrast, pre-excited typical AVNRT terminates after atrial activation, secondary to anterograde block down the slow AVN pathway.

Tachycardia termination or prolongation of the VA (and VH) interval and TCL with transient RBBB, caused by mechanical trauma or introduction of VES, is diagnostic of antidromic AVRT using a right-sided or septal BT and excludes preexcited AVNRT. Continuation of an SVT at the same TCL, despite anterograde block in the BT (by drugs, mechanical trauma caused by catheter manipulation, or ablation), excludes antidromic AVRT.

Diagnostic Maneuvers During Tachycardia

Programmed Atrial Stimulation During Tachycardia

Orthodromic AVRT

Resetting. AES can easily reset orthodromic AVRT. In fact, it is usual for AES not to affect the SVT because of the large size and large excitable gap of the reentrant circuit. However, this can be influenced by the distance between the site of atrial stimulation and the atrial region incorporated in the AVRT circuit (i.e., atrial myocardium between the BT and the AVN). Because only parts of the atrium ipsilateral to the BT are requisite components of the orthodromic AVRT circuit, AES delivered in the contralateral atrium may not affect the circuit, whereas

AESs delivered at sites in close proximity to the BT or the AVN have the highest success at resetting the reentrant circuit.

AES over a wide range of coupling intervals can reset orthodromic AVRT via conduction down the AVN-HPS. In this setting, atrial activation is a fusion of the AES and the SVT impulse traveling retrogradely up the BT. The next QRS can be early or late, depending on the degree of slowing of conduction of the AES anterogradely down the AVN (i.e., the degree of prolongation of the A2-H2 interval).

Termination. An early-coupled AES can terminate the SVT, usually by block in the AVN-HPS. In this setting, the SVT terminates with an AES not followed by a QRS (i.e., AV block). Alternatively, the AES can render the atrium refractory to the SVT impulse traveling retrogradely up the BT, in which case the SVT terminates with an AES followed by a QRS (i.e., VA block). The AES can also anterogradely penetrate the BT and collide with the retrogradely traveling SVT wavefront (VA block). Lastly, the AES can conduct down the AVN-HPS and advance the next QRS, which then blocks in the still-refractory BT or atrium (VA block).

Atrial entrainment. Atrial pacing at a CL approximately 10 to 30 milliseconds shorter than the TCL can generally entrain orthodromic AVRT (Fig. 18.40).

Resetting and entrainment with manifest atrial fusion. Resetting and entrainment with manifest atrial fusion can be demonstrated in AVRT. The morphology of the fusion P wave is hybrid between the tachycardia P wave morphology and the fully paced P wave morphology. This can be difficult to demonstrate if the P waves cannot be visualized on the surface ECG (due to overlapping ST-T wave), which is usually the case; however, manifest fusion can be demonstrable on intracardiac recordings (see Fig. 18.40). Atrial fusion results from intraatrial collision of the impulse propagating from the paced site with the tachycardia impulse emerging from the BT. In contrast, manifest fusion cannot be demonstrated during resetting or entrainment of AVNRT. For atrial fusion (i.e., fusion of atrial activation from both the tachycardia wavefront and the AES) to occur, the AES should be able to enter the reentrant circuit, while at the same time the tachycardia wavefront should be able to exit the circuit. This requires spatial

Fig. 18.40 Atrial Entrainment of Orthodromic Atrioventricular Reentrant Tachycardia (AVRT). Overdrive atrial pacing is from the high right atrium (HRA) during an AVRT using a left lateral bypass tract (BT). Note that the atrial activation sequence during entrainment (blue shade) is different from the tachycardia atrial activation sequence (yellow shade), and is also different from the expected purely paced atrial activation sequence as evidenced by a distal-to-proximal activation sequence in the coronary sinus. This indicates the presence of atrial fusion (between the paced and tachycardia wavefronts) during entrainment, which is consistent with AVRT and excludes both focal atrial tachycardia and atrioventricular nodal reentrant tachycardia. Note that the ventriculoatrial (VA) interval (dashed lines) of the return cycle after cessation of atrial pacing is similar to that of the supraventricular tachycardia (VA linking), because retrograde VA conduction of the last entrained QRS is mediated by the BT. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; RVA, right ventricular apex.

separation between the entry and exit sites to the reentrant circuit, a condition that seems to be lacking in the setting of AVNRT.^{38,39}

Ventriculoatrial linking. The initial atrial complex following cessation of atrial pacing entraining orthodromic AVRT is *linked* to, and cannot be dissociated from, the last captured ventricular complex. As a consequence, the VA intervals of the return cycle after cessation of atrial pacing are fixed and similar to those during tachycardia (with less than 10 milliseconds of variation) after different attempts at SVT entrainment (see Fig. 18.40). The postpacing VA intervals typically remain constant regardless of the site, duration, or CL of the entraining atrial pacing drive because the timing of atrial activation is dependent on retrograde VA conduction of the last entrained QRS mediated by the BT, which is fixed and constant. VA linking is also observed after introduction of an AES with a wide range of coupling intervals during tachycardia. VA linking can also be observed in typical AVNRT but not AT.^{34,40}

Antidromic AVRT. AES is of value in distinguishing antidromic AVRT from preexcited AVNRT. A late-coupled AES, delivered close to the BT atrial insertion site during SVT when the AV junctional atrium is refractory (i.e., when the atrial electrogram is already manifest in the HB recording at the time of AES delivery) that advances (accelerates) the timing of both the next ventricular activation and the subsequent atrial activation, proves that the SVT is an antidromic AVRT using an AV BT anterogradely, and excludes preexcited AVNRT (Fig. 18.41A). Because the AV junctional atrium is refractory at the time of the AES, the AES cannot penetrate the AVN; hence, resetting of the SVT by such an AES is therefore incompatible with AVNRT.

Also, an AES delivered during the SVT that advances ventricular activation and does not influence the VA interval excludes preexcited AVNRT and is diagnostic of antidromic AVRT (see Fig. 18.41A). The VA interval should change in the setting of preexcited AVNRT because the AES penetrates the AVN, producing slower conduction down the AVN slow pathway before the reentrant wavefront conducts retrogradely over the fast pathway and activates the atrium. As a consequence, the delay in atrial activation is expected to produce a longer VA interval, given the presence of a fixed AV interval in response to the AES (mediated by anterograde conduction down the bystander BT in the setting of preexcited AVNRT). In addition, the advanced ventricular activation (resulting from anterograde conduction of the AES over the bystander BT) can potentially invade and capture the HB retrogradely and conduct up the fast AVN pathway and reset the AVNRT circuit. Then the VH interval of the advanced QRS plus the HA interval in response to this QRS should add up to the same VA interval on an undisturbed AVNRT, which is clearly unlikely.

Exact atrial and ventricular capture by an AES delivered when the AV junction is depolarized excludes AVNRT (see Fig. 18.41A). An AES that captures the ventricle at the same coupling interval as that of the AES indicates that the atrial stimulation site is inside the reentrant circuit, because if there were intervening atrial tissue between the stimulation site and the tachycardia circuit (as is the case during AVNRT), the AV interval would prolong, and consequently, the V-V interval would exceed the AES coupling interval.

The presence of a fixed and short VH interval during entrainment of the SVT with atrial pacing suggests antidromic AVRT, and makes AVNRT unlikely (but does not exclude AVNRT). Moreover, failure of entrainment by atrial pacing to influence the VA interval during SVT excludes preexcited AVNRT.

An early-coupled AES can terminate antidromic AVRT by retrograde block in the AVN-HPS (the SVT terminates with an AES followed by a QRS; i.e., VA block; see Fig. 18.41B) or by anterograde block in the BT (the SVT terminates with an AES not followed by a QRS; i.e., AV block; see Fig. 18.41C).

Programmed Ventricular Stimulation During Tachycardia

Orthodromic AVRT

Resetting. VES can easily reset orthodromic AVRT, and is frequently capable of terminating the tachycardia (Fig. 18.42).³⁴ However, the ability of the VES to affect the SVT depends on the distance between the site of ventricular stimulation to the ventricular insertion site of the BT and on the VES coupling interval. Because only parts of the ventricle ipsilateral to the BT are requisite components of the orthodromic AVRT circuit, a VES delivered in the contralateral ventricle may not affect the circuit. However, failure to reset (advance or delay) atrial activation with an early-coupled VES and at different VES coupling intervals, despite advancement of the local ventricular activation at all sites (including the site of the suspected BT) by more than 30 milliseconds, excludes orthodromic AVRT and the presence of a retrogradely conducting BT.⁴¹

Preexcitation index. The preexcitation index analyzes the degree of prematurity (coupling interval) of the latest coupled VES (delivered from the RV apex) that is capable of resetting the tachycardia. Later coupled VESs with a relative preexcitation index (the ratio of the VES coupling interval to the TCL) of more than 90% suggests that the BT is close to the site of ventricular stimulation (i.e., right-sided or septal BT). An absolute preexcitation index (TCL minus VES coupling interval) of at least 75 milliseconds suggests a left free-wall BT; an index of less than 45 milliseconds suggests a septal BT; and an index of 45 to 75 milliseconds is indeterminate. AVNRT would require even earlier coupled VESs and could be distinguished from AVRT if the absolute preexcitation index was greater than 100 milliseconds.⁴²

VES during HB refractoriness. A VES delivered when the HB is refractory (i.e., when the His potential is already manifest or within 35 to 55 milliseconds before the time of the expected His potential) that advances (accelerates, i.e., makes it activate earlier than expected) the next atrial activation is diagnostic of the presence of a retrogradely conducting BT. Such a VES has to conduct and advance atrial activation via a BT because the HPS-AVN is already refractory and cannot mediate retrograde conduction of the VES to the atrium (see Fig. 18.42). Although such an observation excludes AVNRT, it does not exclude AT or prove orthodromic AVRT, and the preexcited atrial activation can reset or even terminate an AT, whereby the BT is an innocent bystander. However, if this VES advances atrial activation with an activation sequence identical to that during the SVT, this suggests that the SVT is orthodromic AVRT and the BT is participating in the SVT, although it does not exclude the rare case of an AT originating at a site close to the atrial insertion site of a bystander AV BT. Furthermore, a VES delivered when the HB is refractory may not affect the next atrial activation if the ventricular stimulation site is far from the BT. Conduction from the ventricular stimulation site to the BT, local ventricular refractoriness, and the TCL all determine the ability of a VES to reach the reentrant circuit before ventricular activation over the normal AVN-HPS.

Although such a VES can advance atrial activation during AT through fast retrograde conduction over a bystander BT, it should not be able to delay an AT beat by conduction over the AV BT. Thus a VES delivered when the HB is refractory that delays the next atrial activation indicates that the VES was conducted with some delay over the BT and that the next atrial activation was dependent on this slower conduction; hence, the BT is participating in the SVT, proving orthodromic AVRT as the mechanism of the SVT. Similarly, a VES delivered when the HB is refractory that terminates the SVT without atrial activation is diagnostic of AVRT.

Exact and paradoxical capture. Exact and paradoxical capture phenomena are diagnostic of AVRT. A VES that captures the atrium at the same coupling interval as that of the VES (exact capture phenomenon) indicates that the ventricular stimulation site is inside the

AES during antidromic AVRT

Fig. 18.41 Atrial Extrastimulation (AES) During Antidromic Atrioventricular Reentrant Tachycardia (AVRT) Using a Left Lateral Bypass Tract (BT). (A) A late-coupled AES delivered when the atrioventricular (AV) junction is refractory (as indicated by lack of advancement of the timing of the local atrial electrogram recording by the His bundle catheter) resets both the next ventricular activation and the subsequent atrial activation. This proves that the supraventricular tachycardia (SVT) is an antidromic AVRT using an AV BT anterogradely, and excludes preexcited atrioventricular nodal reentrant tachycardia (AVNRT). In addition, the reset ventricular activation occurs at a coupling interval identical to the AES coupling interval (i.e., exact coupling phenomenon), and the ventriculoatrial (VA) interval following the AES remains similar to that during SVT, which is consistent with antidromic AVNRT. (B) Late-coupled AES delivered when the AV junction is refractory advances the subsequent QRS and terminates the SVT by retrograde block in the His-Purkinje system–atrioventricular node. (C) An earlier AES terminates the SVT without conduction to the ventricle (i.e., anterograde block in the BT). The AES advances the timing of AV junctional atrial activation. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; HRA, high right atrium; RVA, right ventricular apex.

reentrant circuit, because if there were intervening tissue involved, the VA interval would increase and, subsequently, the A-A interval would exceed the VES coupling interval. Similarly, a VES that captures the atrium at a shorter coupling interval than that of the VES (paradoxical capture phenomenon) indicates that the ventricular stimulation site is not only inside the reentrant circuit but also closer to the ventricular insertion site of the BT than the initial site of ventricular activation

over the AVN-HPS during the SVT, so that the VA interval following the VES is shorter than that during the SVT. This is easier to demonstrate with RV apical pacing during orthodromic AVRT mediated by a right-sided BT.

Termination. Termination of orthodromic AVRT by VES can occur secondary to block of the VES retrogradely in the BT, conduction of the VES retrogradely over the AVN-HPS with or without conduction

VES during orthodromic AVRT

Fig. 18.42 Ventricular Extrastimulation (VES) During Orthodromic Atrioventricular Reentrant Tachycardia (AVRT) Using a Left Lateral Bypass Tract (BT). (A) A late-coupled VES delivered when the His bundle (HB) is refractory (as indicated by lack of advancement of the timing of the His potential) fails to reset the supraventricular tachycardia (SVT). (B) An earlier VES fails to advance the timing of the HB but advances the subsequent atrial activation, indicating the presence of a retrogradely conducting BT, and suggests orthodromic AVRT. Note that the reset atrial impulse is followed by a prolonged atrial–His bundle (AH) interval caused by decremental anterograde conduction in the atrioventricular node (AVN). However, the local ventriculoatrial (VA) interval (retrograde BT conduction) remains constant. (C) An earlier VES delivered before the HB is refractory resets the subsequent atrial activation and terminates the SVT by anterograde atrioventricular block in the AVN. (D) A more premature VES terminates the SVT by retrograde VA block in the BT, excluding atrial tachycardia, but can still occur in atrioventricular nodal reentrant tachycardia because the VES is delivered before anterograde activation of the HB and could potentially penetrate the AVN. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; HRA, high right atrium; RVA, right ventricular apex.

up the BT, or retrograde conduction of the VES up the BT and preexcitation of the atrium and subsequent anterograde block in the AVN-HPS (the most common mechanism) (see Fig. 18.42). Termination of SVT with a single VES strongly suggests orthodromic AVRT as the mechanism of SVT in three settings: (1) when the VES is late-coupled (greater than 80% of TCL); (2) when the TCL is less than 300 milliseconds; and (3) when the VES is delivered during HB refractoriness and is associated with no atrial activation.

Ventricular entrainment. Ventricular pacing at a CL approximately 10 to 30 milliseconds shorter than the TCL can easily entrain AVRT. Although the mere demonstration of the tachycardia does not help discrimination between the different SVT mechanisms, several parameters during ventricular entrainment can help establish the lower portion of the tachycardia circuit as macroreentrant involving the HPS/ventricle (AVRT) or not (AVNRT), including the presence of manifest fusion, VA interval during ventricular pacing as compared with that during SVT, the postpacing interval (PPI), and differential-site ventricular entrainment.⁴³

Manifest ventricular fusion. A requirement for the presence of fusion is spatial separation between the sites of entrance to and exit from the reentrant circuit. In orthodromic AVRT, the entrance and exit of the reentrant circuit (to and from ventricular tissue) are separated from each other, the entrance being from the HPS and the exit being at the BT ventricular insertion site. In this setting, the paced wavefront can activate a portion of the ventricles and enter the AVRT circuit and at the same time the tachycardia wavefront emerge from the reentry circuit at a distant exit site and activate another part of the ventricles. Also, the relative proximity of the pacing site to the entry and exit sites

of the reentry circuit, is a critical determinant for the occurrence of fusion during resetting and entrainment. Pacing at a site closer to the BT ventricular insertion site (e.g., LV pacing in the setting of left free-wall BTs, and RV basal pacing in the setting of right-sided or septal BTs) than the entrance of the reentrant circuit to ventricular tissue (i.e., the HPS) would result in a larger degree of fusion of QRS morphology between baseline morphology during orthodromic AVRT and that of fully paced QRS (Fig. 18.43).⁴⁴

Manifest ventricular fusion during SVT entrainment is proof that the ventricle is part of the SVT circuit (i.e., diagnostic of AVRT). On the other hand, such phenomena cannot occur during AVNRT and AT because of the lack of spatial separation of the entrance and exit of the AVNRT or AT circuit to the ventricles and because the ventricles are not an obligatory part of that circuit.

Δ VA interval. Entrainment of the SVT by RV pacing can help differentiate orthodromic AVRT from AVNRT by evaluating the VA interval during SVT (measured from the onset of surface QRS to high RA electrogram) versus the VA interval during pacing (i.e., the SA interval, measured from the ventricular pacing stimulus to the high RA electrogram). The ventricle and atrium are activated in sequence during orthodromic AVRT and during ventricular pacing, but in parallel during AVNRT. Therefore the VA interval during orthodromic AVRT approximates that during ventricular pacing (see Fig. 18.43). In contrast, the VA interval during AVNRT would be much shorter than that during ventricular pacing (see Fig. 17.19). In general, a difference in the VA interval (Δ VA [$VA_{\text{pacing}} - VA_{\text{SVT}}$]) greater than 85 milliseconds is consistent with AVNRT, whereas a Δ VA of less than 85 milliseconds is consistent with orthodromic AVRT (see Fig. 20.14).^{45,46}

Fig. 18.43 Ventricular Entrainment of Orthodromic Atrioventricular Reentrant Tachycardia (AVRT) Using a Concealed Superoparaseptal Bypass Tract. Note that the Δ VA interval ($VA_{\text{pacing}} - VA_{\text{SVT}}$) is less than 85 milliseconds and the (PPI - TCL) is less than 115 milliseconds, both of which favor orthodromic AVRT over atrioventricular nodal reentrant tachycardia (AVNRT). In addition, ventricular fusion (between the paced and tachycardia wavefronts) is observed during entrainment (right, pure paced QRS morphology), which is consistent with AVRT and excludes AVNRT. Comparing the HA interval during the tachycardia (left) with that during ventricular pacing during normal sinus rhythm at the TCL (right) demonstrates that the Δ HA interval ($HA_{\text{pacing}} - HA_{\text{SVT}}$) is -43 milliseconds, which favors orthodromic AVRT over AVNRT; the HA interval is measured from the end of the His potential to the atrial electrogram in the high right atrium (HRA). CS_{dist} , Distal coronary sinus; CS_{prox} , proximal coronary sinus; HA, His bundle-atrial; PPI, postpacing interval; RVA, right ventricular apex; SVT, supraventricular tachycardia; TCL, tachycardia cycle length; VA, ventriculoatrial.

Postpacing interval. The PPI reflects conduction time from the ventricular pacing site to the SVT circuit, once around the reentry circuit, and then back to the pacing site. The difference between the PPI and TCL ($PPI - TCL$) represents the conduction time from the pacing site to the reentry circuit and back. Thus the ($PPI - TCL$) difference can qualitatively estimate how far the reentrant circuit is from the pacing site; the greater the ($PPI - TCL$) difference, the longer the conduction time between the pacing site and reentry circuit, and the greater the “electrical” distance is between the pacing site and the circuit.

The reentry circuit in AVRT involves the BT, ipsilateral atrium, AVN-HB, and ipsilateral bundle branch and ventricle. On the other hand, the circuit of AVNRT (typical or atypical) is confined above the HB. Because the RV is closer to the AVRT circuit as compared to the AVNRT circuit, the ($PPI - TCL$) difference following entrainment from the RV apex is smaller in the setting of AVRT than during AVNRT (see Fig. 18.43). In fact, a ($PPI - TCL$) difference of more than 115 milliseconds was found to identify AVNRT, whereas a ($PPI - TCL$) difference of less than 115 milliseconds was consistent with orthodromic AVRT. For borderline values, ventricular pacing at the RV base can help exaggerate the ($PPI - TCL$) difference in the setting of AVNRT, but without significant changes in the setting of orthodromic AVRT (see differential-site RV entrainment later).^{47,48}

A relatively common phenomenon encountered during entrainment of orthodromic AVRT by ventricular pacing is the prolongation of the AH interval because of either decremental conduction properties of the AVN or (in the presence of dual AVN physiology) a jump of antero-grade conduction from the fast pathway to the slow pathway. The prolonged AH interval on the last entrained beat will contribute to prolongation of the PPI that is not reflective of the distance of the pacing site from the circuit. Thus the ($PPI - TCL$) differences obtained after entrainment of orthodromic AVRT employing a septal BT can actually overlap with those observed after entrainment of AVNRT. “Correction” of the PPI by subtracting the increment in AVN conduction time in the first PPI (postpacing AH interval minus prepacing AH interval) from the ($PPI - TCL$) difference (“corrected” [$PPI - TCL$]) has been found to improve the accuracy of this criterion. The difference between AV intervals (postpacing AV interval minus prepacing AV interval) can be taken for the latter adjustment when a His deflection is not clearly visible (assuming the HV interval remains constant). A corrected ($PPI - TCL$) difference of less than 110 milliseconds was found to be more accurate in distinguishing orthodromic AVRT from AVNRT than the uncorrected ($PPI - TCL$) difference.^{49,50}

Furthermore, during orthodromic AVRT, the corrected ($PPI - TCL$) difference can help localize the BT used for retrograde conduction. The RV apical pacing site is closer to the reentrant circuit of orthodromic AVRT utilizing a right-sided BT than orthodromic AVRT utilizing a left-sided BT. Hence, as expected, the corrected ($PPI - TCL$) difference is shorter (less than 55 milliseconds) in patients with orthodromic AVRT with a right-sided BT when pacing the RV apex. Patients with left-sided BTs typically have a corrected ($PPI - TCL$) difference of more than 55 milliseconds.⁵¹

Of note, determinations of the corrected ($PPI - TCL$) and ΔVA ($VA_{\text{pacing}} - VA_{\text{SVT}}$) after resetting with single or double VESs from the RV apex, is of similar value for discrimination between AVNRT and orthodromic AVRT, even when the SVT is interrupted by ventricular pacing. Corrected ($PPI - TCL$) of more than 110 milliseconds and ΔVA of more than 110 milliseconds after resetting identify AVNRT.⁵²

Importantly, there are several potential pitfalls of the ΔVA interval and the PPI criteria discussed previously. The TCL and VA interval are often perturbed for a few cycles after entrainment. For this reason, care should be taken not to measure unstable intervals immediately after ventricular pacing. In addition, oscillations in the TCL and VA intervals

can occur spontaneously during the SVT. The discriminant points chosen may not apply when the spontaneous variability is greater than 30 milliseconds. Also, it is possible to mistake isorhythmic VA dissociation for entrainment if the pacing train is not long enough or the PCL is too close to the TCL. Furthermore, this test is less reliable and should be used with caution in patients with left lateral BTs.

In addition, these criteria may not apply to BTs with significant decremental properties, although small decremental intervals are unlikely to provide a false result. A higher cutoff value of 125 milliseconds was found to increase the sensitivity for orthodromic AVNRT while maintaining high specificity. Slow, decremental BT conduction can also affect the sensitivity of the ΔVA criteria for orthodromic AVRT, but the specificity remains high. Therefore, if any standard criteria positive for orthodromic AVRT ($PPI - TCL < 115$ milliseconds, corrected [$PPI - TCL$] < 110 milliseconds, and $\Delta VA < 85$ milliseconds) is diagnostic of orthodromic AVRT, despite discordance among each other (which can occur about 50% of the time).⁴³

Differential-site RV entrainment. Differential-site RV entrainment (from RV apex vs. RV base) can help distinguish AVNRT from orthodromic AVRT. Because the reentrant circuit in AVNRT is confined above the HB and does not involve the ventricle, the base of the RV is electrically more distant (although anatomically closer) to the tachycardia circuit than the RV apex, given that the His-Purkinje network directly inserts near the RV apex. Consequently, the PPI after entrainment of AVNRT from the RV base is longer than that following entrainment from the RV apex. The difference in PPI from the RV base versus the RV apex is largely composed of the extra time required to reach the circuit from the base versus the apex (approximately 30 milliseconds). Conversely, in orthodromic AVRT, in which the ventricles are an obligatory part of the circuit, the basal pacing site relative to the RV apex is variably related to the circuit, closer than the RV apex with septal BTs and equidistant with free-wall BTs, but the paced wavefront from either the RV apex or RV base tends to have, on average, approximately equal access and proximity to the reentrant circuit involved in orthodromic AVRT. Therefore the time taken to reach the circuit (and hence the PPI) tends to be similar, irrespective of the location of the BT.

Correction of the PPI (to avoid potential error introduced by decremental conduction within the AVN during ventricular pacing) increases the accuracy of this method, although the degree of decrement is not expected to be materially different from basal rather than apical pacing as long as the pacing rates are the same or similar. The “corrected PPI” is obtained by subtracting any increase in the AV interval of the return cycle beat (as compared with the AV interval during SVT). A differential corrected ($PPI - TCL$) difference of more than 30 milliseconds after transient entrainment was found to be consistent with AVNRT (i.e., corrected [$PPI - TCL$] difference following pacing from the RV base was consistently at least 30 milliseconds longer than that following pacing from the RV apex). In contrast, a corrected ($PPI - TCL$) difference of less than 30 milliseconds was observed in all cases of orthodromic AVRT. In addition, a differential VA interval (VA interval during entrainment from RV base versus RV septum) of more than 20 milliseconds was consistent with AVNRT, whereas a differential VA interval of less than 20 milliseconds was consistent with orthodromic AVRT.^{53,54}

The main advantage of this technique is that the differential VA interval can be calculated from the last paced beat if the tachycardia is terminated after transient entrainment.

Length of pacing drive required for entrainment. Assessing timing and type of response of SVT to RV pacing can also help differentiate orthodromic AVRT from AVNRT. In the setting of orthodromic AVRT, ventricular tissue is the only intervening tissue between the pacing wavefront and the ventricular insertion site of the BT. Therefore once ventricular capture is achieved during RV pacing, the paced wavefront

propagates to the ventricular insertion site of the BT quickly and resets the tachycardia. Consequently, RV pacing results in a faster response of resetting the tachycardia. In the setting of AVNRT, the pacing site is distant from the SVT circuit, and the paced wavefront has to propagate through ventricular tissue, then through the HPS followed by AVN tissue prior to resetting the tachycardia. As a consequence, resetting of AVNRT is delayed for several captured paced beats as compared with orthodromic AVRT.

After initiation of synchronized RV pacing during SVT at a CL that is 10 to 40 milliseconds shorter than the TCL, once constant-appearing QRS complexes (as evidenced by fixed pacing morphology of the surface ECG, either pure paced morphology or fixed QRS fusion) are observed, the number of RV paced beats required to accelerate the SVT to the PCL is determined. The first atrial capture beat accelerated to the PCL is identified by demonstrating a fixed ventricular SA capture interval. One report demonstrated that using a cutoff of one beat to accelerate the SVT to the PCL could identify all orthodromic AVRT cases and essentially exclude all cases of AVNRT with high accuracy. On the contrary, if two or more beats are required to accelerate SVT to the PCL, this can distinguish AVNRT from orthodromic AVRT with very high confidence as well (see Fig. 20.13).

The major advantage of this method is its independence of tachycardia continuation after cessation of pacing. However, it is likely that these criteria may not be applicable at PCLs more than 40 milliseconds shorter than the TCL or prematurity of more than 80% of the TCL because resetting of the tachycardia can occur earlier in AVNRT in response to a greater degree of penetration into the tachycardia circuit. In addition, these findings may not apply in cases in which AVNRT occurs in the setting of a bystander BT because SVT may be reset using the bystander BT. In addition, although this technique is effective for differentiating septal pathways from atypical AVNRT, it may be less useful in patients with BTs remote from the pacing stimulus (e.g., left free-wall BTs) (see Fig. 20.15).⁵⁵

Atrial resetting during the transition zone. On initiation of RV pacing trains during SVT at a rate slightly faster than the TCL, there is a transition zone during which the pacing train fuses with anterograde ventricular activation (i.e., the zone in which the paced QRS complexes show progressive fusion with the SVT complexes) until stable QRS morphology is observed (either completely paced or constantly fused). The transitional zone begins with progressive fusion beats between the paced and tachycardia wavefronts and ends with the first beat of stable QRS morphology, the latter representing constant fusion in the case of orthodromic AVRT and a fully paced QRS morphology in patients with AVNRT. In patients with AVNRT or AT, acceleration of the timing of atrial activation cannot occur through the AVN during the transition zone. The reason is that the HB is expected to be refractory, as indicated by at least some ventricular activation still occurring by anterograde conduction over the HPS. If perturbation of atrial timing occurs during the transition zone, it indicates the presence of a retrogradely conducting BT, which can be an integral part of the SVT circuit (i.e., orthodromic AVRT) or a bystander (Fig. 18.44). In one report, these criteria showed excellent diagnostic accuracy and could be applied regardless of whether entrainment was achieved or whether the SVT terminated during pacing. Perturbation of atrial timing of at least 15 milliseconds or a fixed SA interval measured from the last beat of the transition zone was seen in all the patients with orthodromic AVRT and in none of the patients with AVNRT or AT (unless a bystander retrogradely conducting BT is present).^{54,56}

Of note, the number of reset beats (defined as fixed SA interval) in the transitional zone (during ventricular overdrive pacing from the RV apex during orthodromic AVRT) depends on the proximity of the BT to the pacing site; hence, it can predict BT location. Right-sided BTs produce reset earlier than left-sided BTs, and a cut-off of more than two beats with a fixed SA interval within the transitional zone was found to successfully discriminate between left-sided and right-sided BTs.⁵⁷

Fig. 18.44 Resetting of Supraventricular Tachycardia (SVT) During the Transition Zone. Overdrive ventricular pacing is started from the RVA at a cycle length (CL) of 420 milliseconds, slightly shorter than the SVT CL (442 milliseconds). On initiation of right ventricular pacing, there is a transition zone during which the paced wavefronts fuse with anterograde ventricular activation, before stable QRS morphology ensues. Note that advancement of atrial activation (resetting) initially occurred during the transition zone, indicating orthodromic atrioventricular reentrant tachycardia as the mechanism of the SVT. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; HRA, high right atrium; RVA, right ventricular apex.

Permanent junctional reciprocating tachycardia. A VES delivered during PJRT can produce decremental conduction in the BT and prolongation of the VA interval, resulting in possible delay of the next atrial activation (i.e., post excitation or delay of excitation; see Fig. 18.39). Such a response excludes AT, and when this occurs in response to a VES delivered when the HB is refractory, it is diagnostic of orthodromic AVRT, and excludes both AT and AVNRT. In addition, a late-coupled VES introduced when the HB is refractory frequently blocks retrogradely in the BT and reproducibly terminates the tachycardia without reaching the atrium, again excluding both AT and AVNRT.⁴³

The ability to preexcite the atrium with a VES introduced when the HB is refractory is difficult to demonstrate in PJRT because of the long conduction time over the BT, the decremental conduction properties of the BT, and the fact that the TCL is just longer than the shortest length at which the BT is capable of retrograde conduction. This can be facilitated by introduction of the PVC at a site closer to the BT ventricular insertion.

Antidromic AVRT. Similar to orthodromic AVRT, ventricular pacing and VES can easily entrain or reset antidromic AVRT because the ventricle is part of the reentrant circuit. Because both orthodromic and antidromic AVRTs use similar reentry circuits, the concepts of resetting and entrainment discussed for orthodromic AVRT also apply, to a large degree, to antidromic AVRT.

Of note, the development of retrograde RBBB following a VES introduced during the SVT can help distinguish antidromic AVRT from AVNRT. When the VES results in retrograde RBBB (i.e., blocks retrogradely in the RB), such RBBB will not change the timing of the next atrial activation in the setting of AVNRT. In contrast, in antidromic AVRT using a right-sided BT, such RBBB will increase the size of the reentrant circuit, because the impulse cannot reach the HB through the RB and has to travel transeptally and then retrogradely over the LB. This results in prolongation in the VA interval and delay in the timing of the next atrial activation. The increment in the VA interval is caused by prolongation of the VH interval and, if RBBB persists, the SVT will have a long VH interval.

Antidromic AVRT can usually be terminated by ventricular pacing. Termination occurs by retrograde invasion and concealment in the BT, resulting in anterograde block over the BT following conduction to the atrium through the AVN.

Para-Hisian Pacing During Tachycardia

Para-Hisian pacing during tachycardia can help discriminate between AVRT and AVNRT. This pacing maneuver is discussed in detail in **Chapter 20**. Briefly, entrainment of the SVT is performed by pacing at the para-Hisian region using the HB catheter at a PCL that is 10 to 30 milliseconds shorter than the TCL. Entrainment is confirmed when the atrial CL accelerates to the PCL, without a change in the atrial activation sequence, and the tachycardia continues after pacing is discontinued.⁵⁸

Para-Hisian entrainment is performed by alternately pacing at high-energy output for HB-RB capture or lower energy output for HB-RB noncapture. Entrainment with HB-RB capture is recorded separately from that without HB-RB capture. The SA and local VA intervals during HB-RB capture and noncapture are then examined.

If para-Hisian entrainment cannot be performed because of repetitive termination of the tachycardia during entrainment attempts, isoproterenol infusion may be used to help sustain the rhythm. Alternatively, single or double VESs can be given to reset the tachycardia (para-Hisian resetting). These VESs are delivered at progressively shorter coupling intervals until the first VES that reliably advances or resets the tachycardia. This is performed alternately with high- or low-energy outputs to achieve HB-RB capture and noncapture, respectively. As with para-Hisian

entrainment, the retrograde atrial activation sequence and timing are compared during para-Hisian resetting to characterize the response.

In AVNRT (typical or atypical), the AVN-AVN pattern is observed in response to para-Hisian entrainment or resetting; that is, both the SA and the local VA intervals increase during HB-RB noncapture compared with HB-RB capture.

In orthodromic AVRT, the BT-BT pattern or BT-BT_L pattern is observed. In the setting of a BT-BT pattern, the SA and local VA intervals are usually not significantly different between HB-RB capture and noncapture. Conversely, in the case of a BT-BT_L pattern, the SA interval increases on HB-RB noncapture, but without significant change in the local VA interval.

A ΔSA interval of less than 40 milliseconds was found to be a reasonable guide to separating the AVN-AVN from the BT-BT response. Patients with AVNRT uniformly have a ΔSA interval of greater than 40 milliseconds, whereas those with AVRT have a ΔSA interval of less than 40 milliseconds (except for rare patients with a left lateral BT). Using the Δ local VA interval (instead of the ΔSA interval) provide a more accurate parameter for discrimination between AVNRT and AVRT.

An AVN-AVN or fusion pattern during para-Hisian entrainment or resetting has not been observed in patients with AVNRT. This is a potential advantage over para-Hisian pacing during NSR in identifying the presence of a BT. Because retrograde VA conduction can only proceed over a single route during entrainment of the SVT (assuming that a complex scenario such as multiple BTs is not present), the various forms of retrograde fusion that might be seen during para-Hisian pacing during NSR cannot occur during para-Hisian entrainment or resetting.

Diagnostic Maneuvers During Sinus Rhythm After Tachycardia Termination

Atrial Pacing at the Tachycardia Cycle Length

Under comparable autonomic tone, the PR and AH intervals during atrial pacing at a CL similar to the TCL should be comparable to those during orthodromic AVRT. These findings are also observed in the setting of AT. In contrast, the AH and PR intervals during atrial pacing would be longer than those during tachycardia in the setting of AVNRT, assuming the slow pathway has been engaged. A ΔAH (AH_{pacing} – AH_{SVT}) of more than 40 milliseconds has been reported to favor AVNRT.⁴⁸

A major limitation of ΔAH criteria, however, is the sensitivity of the AVN to rapid fluctuations in autonomic tone so that comparison of AH intervals between tachycardia and pacing should be done close in time, allowing for minimal change in the autonomic state of the patient.⁴³

Ventricular Pacing at the Tachycardia Cycle Length

Under comparable autonomic tone status, 1:1 VA conduction over the AVN should be maintained during ventricular pacing at a CL similar to the TCL. If VA block develops during ventricular pacing, orthodromic AVRT is unlikely, and AT and AVNRT are favored.

In addition, ventricular pacing during NSR at a PCL similar to the TCL results in HA and VA intervals that are shorter than those during orthodromic AVRT because the HB and atrium are activated sequentially during orthodromic AVRT but in parallel during ventricular pacing whereby the atrium is activated via the BT (see Fig. 18.43). To help distinguish between orthodromic AVRT and AVNRT, the HA interval is measured from the *end* of the His potential (where the impulse leaves the HB to enter the AVN) to the atrial electrogram in the high RA recording and the ΔHA interval (HA_{pacing} – HA_{SVT}) is calculated. In the setting of orthodromic AVRT the ΔHA interval is typically less than –10 milliseconds. In contrast, in the setting of AVNRT the ΔHA interval is typically more than –10 milliseconds because the HA interval during

AVNRT is shortened by parallel activation of both the HB and the atrium during the tachycardia (i.e., the HA interval is a “pseudo-interval” that represents activation times of the HB and atrium), whereas the HB and atrium are activated sequentially during ventricular pacing in the absence of a BT (i.e., the HA interval represents a true conduction time interval from the HB to the atrium). The Δ HA interval is even more pronounced in atypical AVNRT, which has a lower common pathway that is longer than that in typical AVNRT. In focal junctional tachycardia, the Δ HA interval is typically close to 0.³⁰

The Δ HA interval criterion has high specificity, sensitivity, and positive predictive accuracy for differentiation between AVNRT and orthodromic AVRT, but it has certain limitations. The main limitation of the Δ HA interval criterion is the ability to record the retrograde His potential during ventricular pacing. The retrograde His potential generally appears before the local ventricular electrogram in the HB tracing, and can be verified by the introduction of a VES that causes the His potential to occur after the local ventricular electrogram. Moreover, pacing from different sites (e.g., midseptum) may allow earlier penetration into the HPS and facilitate observation of a retrograde His potential. When the retrograde His potential is not visualized, using the Δ VA interval instead of the Δ HA interval is not as accurate in discriminating orthodromic AVRT from AVNRT. Another limitation is that VA conduction during ventricular pacing may not occur over the BT but propagates preferentially over the HPS-AVN, leading to earlier atrial activation over this pathway than over the BT. If this were the case, the HA interval during ventricular pacing would be shorter than that observed if the atrium were activated via the BT. This would yield a more negative Δ HA interval.

It is important to recognize that the atrial activation sequence during ventricular pacing can be mediated by retrograde conduction over the BT, over the AVN, or a fusion of both, and consequently it can be similar to or different from that during orthodromic AVRT.

Exclusion of Other Arrhythmia Mechanisms

AVNRT and AT arising near the AV groove can mimic orthodromic AVRT and, in the presence of a manifest BT, those tachycardias can be associated with ventricular preexcitation mimicking antidromic AVRT, whereby the BT is functioning as an innocent bystander. Therefore EP testing is required, not just to identify the presence of a BT, but also to define its role in any clinical or inducible arrhythmia. Boxes 18.4 and 18.5 summarize the EP findings indicative of the presence of a BT and its potential participation in an inducible SVT. Exclusion of other SVT mechanisms is necessary because the mere presence of a BT is not adequate to make a diagnosis and a treatment strategy (Boxes 18.6–18.8).

Furthermore, the presence of multiple BTs is not infrequent, and careful EP testing is required to evaluate this possibility. Several clinical

and EP findings are indicative of the presence of multiple BTs (Box 18.9; Figs. 18.45 and 18.46; see eFig. 18.1). However, despite these various methods, many BTs are not identified until after catheter ablation of the first BT. Failure to detect the presence of multiple BTs during EP testing has been reported in as many as 5% to 15% of patients. This may be explained by the fact that changes in the preexcitation pattern can be subtle in shifting from one BT to another. Furthermore, one BT can preferentially conduct during atrial pacing or participate in preexcited tachycardias while another BT can be responsible for the retrograde limb during orthodromic AVRT or ventricular pacing. In addition, there may be fusion of BT conduction, anterograde or retrograde. Repetitive concealed conduction into the BT during AVRT may also preclude identification of that BT before ablation of the first BT.

LOCALIZATION OF THE BYPASS TRACT

Several EP techniques can help map the location of the AV BT and guide catheter ablation (Box 18.10). Those techniques are best used in combination to improve mapping accuracy and ablation outcome.

Pacing From Multiple Atrial Sites

The closer the pacing site to the BT atrial insertion, the more rapidly the impulse reaches the BT relative to the AVN and, thus, the greater the degree of preexcitation and the shorter the P-delta interval. This method is especially helpful when the BT cannot conduct retrogradely, prohibiting localization with atrial mapping during SVT or ventricular pacing.

Preexcitation Index

The preexcitation index analyzes the coupling interval of the VES (delivered from the RV) that resets orthodromic AVRT as a percentage of the TCL. A relative preexcitation index (the ratio of the coupling interval to the TCL) of more than 90% of a VES that advances atrial activation during orthodromic AVRT suggests that the BT is close to the site of ventricular stimulation (i.e., RV or septal BT). An absolute preexcitation index (TCL minus VES coupling interval) of at least 75 milliseconds suggests a left free-wall BT, an index of less than 45 milliseconds suggests a septal BT, and an index of 45 to 75 milliseconds is indeterminate.

BOX 18.4 Electrophysiological Findings Indicating Presence of Retrograde Atrioventricular Bypass Tract Function

- Eccentric atrial activation sequence during ventricular pacing
- RV apical pacing producing longer VA interval and/or different atrial activation sequence compared with that during RV basilar pacing
- Para-Hisian pacing producing similar VA interval with and without HB capture or producing different atrial activation sequence depending on whether the HB is captured
- VES delivered when the HB is refractory advances the next atrial activation during SVT

HB, His bundle; RV, right ventricular; SVT, supraventricular tachycardia; VA, ventriculoatrial; VES, ventricular extrastimulus.

BOX 18.5 Electrophysiological Findings Indicating Presence and Participation of Atrioventricular Bypass Tract in Supraventricular Tachycardia

- VES delivered during SVT when the HB is refractory terminates the SVT without atrial activation.
- VES delivered during SVT when the HB is refractory delays the next atrial activation.
- VES during SVT captures the atrium at the same coupling interval as that of the VES (exact capture phenomenon).
- VES delivered during SVT captures the atrium at a shorter coupling interval than that of the VES (paradoxical capture phenomenon).
- VA interval (with or without concomitant prolongation in TCL) prolonged during the SVT secondary to the development of BBB.
- Entrainment of the SVT by ventricular pacing results in prolongation of the VA interval ($VA_{\text{pacing}} > VA_{\text{SVT}}$).

BBB, Bundle branch block; HB, His bundle; SVT, supraventricular tachycardia; TCL, tachycardia cycle length; VA, ventriculoatrial; VES, ventricular extrastimulus.

BOX 18.6 Exclusion of Atrial Tachycardia**Effects of BBB**

- Prolongation of surface VA interval during SVT (with or without TCL prolongation) on development of BBB excludes AT.

Oscillations in TCL

- Spontaneous changes in TCL accompanied by constant VA interval (VA linking) exclude AT.
- Changes in atrial CL that are predicted by the change in the preceding ventricular CL argue against AT.

VES During SVT

- VES that terminates the SVT without atrial activation excludes AT.
- VES that delays the next atrial activation excludes AT.
- VES during SVT that captures the atrium at the same coupling interval as that of the VES (exact capture phenomenon) excludes AT.
- VES delivered during SVT that captures the atrium at a shorter coupling interval than that of the VES (paradoxical capture phenomenon) excludes AT.
- When a VES delivered during HB refractoriness advances the next atrial activation with an atrial activation sequence similar to that during SVT, AT is unlikely.
- Manifest ventricular fusion during resetting excludes AT.

Overdrive Ventricular Pacing During SVT

- If atrial activation sequence during ventricular entrainment is similar to that during the SVT, AT is less likely.

- Presence of A-V electrogram sequence at cessation of ventricular pacing generally excludes AT.
- Manifest ventricular fusion during entrainment indicates AVRT and excludes AT.

Overdrive Atrial Pacing During SVT

- If the VA interval following the last entrained QRS is reproducibly constant (with <10 msec variation), despite pacing at different CLs or for different durations (VA linking) and similar to that during TCL, AT is unlikely.
- If the VA interval following the last entrained QRS is reproducibly constant (with <14-msec variation), despite pacing at different atrial sites (VA linking), AT is unlikely.
- Demonstration of entrainment with manifest atrial fusion excludes focal AT.

Atrial Pacing During NSR at Tachycardia CL

- If the VA interval following the last entrained QRS is reproducibly constant (with <10-msec variation), despite pacing at different CLs or for different durations (VA linking) and similar to that during TCL, AT is unlikely.
- If the VA interval following the last entrained QRS is reproducibly constant (with <14-msec variation), despite pacing at different atrial sites (VA linking), AT is unlikely.

Ventricular Pacing During NSR at Tachycardia CL

- If retrograde atrial activation sequence during ventricular pacing is similar to that during SVT, AT is less likely.

AT, Atrial tachycardia; AVRT, atrioventricular reentrant tachycardia; BBB, bundle branch block; CL, cycle length; HB, His bundle; NSR, normal sinus rhythm; SVT, supraventricular tachycardia; TCL, tachycardia cycle length; VA, ventriculoatrial; VES, ventricular extrastimulus.

BOX 18.7 Exclusion of Atrioventricular Nodal Reentrant Tachycardia**SVT Induction by VES**

- $\Delta VA (VA_{VES} - VA_{SVT}) < 85$ msec favors orthodromic AVRT over AVNRT.
- $(PPI_{VES} - TCL) < 115$ msec favors orthodromic AVRT over AVNRT.

Atrial Activation Sequence

- Eccentric atrial activation sequence during the SVT excludes AVNRT (with the exception of left variant AVNRT).

Effects of BBB

- Prolongation of VA interval or TCL on development of BBB excludes AVNRT.

Oscillations in TCL

- Spontaneous changes in TCL accompanied by constant VA interval (VA linking) make AVNRT unlikely.

Differential RV Pacing

- If the atrial activation sequence changes during pacing at the RV apex versus pacing at the RV base, AVNRT is less likely.
- If the SA interval is shorter with pacing from the base than from the apex at the same PCL, AVNRT is less likely.

VES During SVT

- VES delivered during SVT when the HB is refractory that resets (advances or delays) or terminates the SVT excludes AVNRT.
- VES during SVT that conducts to the atrium at the same coupling interval as that of the VES (exact capture phenomenon) excludes AVNRT.
- VES delivered during SVT that conducts to the atrium at a shorter coupling interval than that of the VES (paradoxical capture phenomenon) excludes AVNRT.

- Manifest ventricular fusion during resetting excludes AVNRT.
- Preexcitation index (the difference between the TCL and the longest VES coupling interval at which atrial capture occurs during tachycardia) ≥ 100 msec characterizes AVNRT, whereas an index <45 msec is consistent with AVRT with a septal BT.
- Corrected $(PPI - TCL) < 110$ msec (after resetting with single or double VESs from the RV apex) argues against AVNRT.

Overdrive Ventricular Pacing During SVT

- ΔVA interval ($VA_{pacing} - VA_{SVT}$) <85 msec argues against AVNRT.
- $PPI - TCL < 115$ msec argues against AVNRT.
- Corrected $PPI - TCL < 110$ msec argues against AVNRT.
- Manifest ventricular fusion during entrainment indicates AVRT and excludes AVNRT.
- Acceleration of the SVT to the PCL occurring after a single captured paced RV complex is consistent with orthodromic AVRT and essentially excludes AVNRT.
- Differential corrected $PPI - TCL$ of <30 msec after transient entrainment from the RV apex versus the RV base is consistent with orthodromic AVRT and excludes AVNRT.
- Differential VA interval (ventricular stimulus-to-atrial interval during entrainment from RV base vs. RV septum) of <20 msec is consistent with orthodromic AVRT and excludes AVNRT.
- Atrial resetting (perturbation of atrial timing by >15 msec) during the transition zone is consistent with orthodromic AVRT and excludes AVNRT or AT (unless a bystander retrogradely conducting BT is present).
- Acceleration of the SVT to the PCL occurring by the first beat with stable paced QRS morphology is consistent with orthodromic AVRT and essentially excludes AVNRT.

BOX 18.7 Exclusion of Atrioventricular Nodal Reentrant Tachycardia—cont'd**AES During SVT**

- Demonstration of resetting with manifest atrial fusion excludes AVNRT.

Overdrive Atrial Pacing During SVT

- ΔAH interval ($AH_{\text{pacing}} - AH_{\text{SVT}}$) < 20 msec excludes AVNRT.
- Demonstration of entrainment with manifest atrial fusion excludes AVNRT.

Para-Hisian Pacing During SVT

- SA and the local VA intervals that remain constant regardless of whether the HB-RB is being captured indicate orthodromic AVRT and exclude AVNRT.
- SA interval prolongation on HB-RB noncapture, but without significant change in the local VA interval, indicates orthodromic AVRT and excludes AVNRT.
- ΔSA interval < 40 msec indicates AVRT (except for rare patients with a left lateral BT) and argue against AVNRT.

- Entry into the tachycardia circuit within 1 beat indicates AVRT, whereas entry into the circuit occurring only after 3 or more beats is consistent with AVNRT.

Atrial Pacing During NSR at Tachycardia CL

- ΔAH interval ($AH_{\text{pacing}} - AH_{\text{SVT}}$) < 20 msec excludes AVNRT.

Ventricular Pacing During NSR at Tachycardia CL

- ΔHA interval of less than -10 msec makes AVNRT unlikely.

Para-Hisian Pacing During NSR

- Para-Hisian pacing producing similar VA interval, regardless of whether HB capture occurs, and/or different atrial activation sequence, depending on whether HB capture occurs, makes AVNRT unlikely.

AES, Atrial extrastimulation; AH, atrial–His bundle; AVNRT, atrioventricular nodal reentrant tachycardia; AVRT, atrioventricular reentrant tachycardia; BBB, bundle branch block; BT, bypass tract; CL, cycle length; HA, His bundle–atrial interval; HB, His bundle; NSR, normal sinus rhythm; PCL, pacing cycle length; PPI, postpacing interval; RB, right bundle branch; RV, right ventricle; SA, stimulus-to-atrial; SVT, supraventricular tachycardia; TCL, tachycardia cycle length; VA, ventriculoatrial; VES, ventricular extrastimulus.

BOX 18.8 Differentiation Between Antidromic Atrioventricular Reentrant Tachycardia and Preexcited Atrioventricular Nodal Reentrant Tachycardia**SVT Features**

- $HA_{\text{SVT}} < 70$ msec excludes antidromic AVRT.
- Positive HV or VH interval ≤ 10 msec (especially when HA interval is ≤ 50 msec) suggests AVNRT.

Termination of SVT

- Continuation of the SVT at the same TCL, despite anterograde block in the BT (by drugs, mechanical trauma, or ablation), is diagnostic of AVNRT and excludes antidromic AVRT.
- Block of the BT by drugs and subsequent induction of narrow-complex SVT with the same TCL, HA interval, and retrograde atrial activation sequence as that of the preexcited SVT induced before the BT block is diagnostic of preexcited AVNRT and excludes antidromic AVRT.
- Termination of SVT in response to carotid sinus massage or adenosine:
 - AVNRT terminates after atrial activation (secondary to anterograde block down the slow pathway).
 - Classic antidromic AVRT terminates after ventricular activation (secondary to retrograde block up the AVN).

Effects of BBB

- Prolongation of surface ECG VA interval (often with prolonged TCL) on development of BBB excludes AVNRT.

SVT Induction With Ventricular Stimulation

- Induction of the SVT by ventricular pacing at a PCL similar to the TCL or by a VES that advances the timing of the His potential by a coupling interval (i.e., H1-H2 interval) similar to the H-H during the SVT, the HA interval following such a VES is compared with that during the SVT:
 - HA_{VES} or $HA_{\text{pacing}} > HA_{\text{SVT}}$ is diagnostic of AVNRT and excludes antidromic AVRT.
 - HA_{VES} or $HA_{\text{pacing}} \leq HA_{\text{SVT}}$ is diagnostic of antidromic AVRT and excludes AVNRT.

AES Delivered During SVT

- Late-coupled AES is delivered close to the BT atrial insertion site during SVT when the AV junctional atrium is refractory. If it advances the timing of both the next ventricular activation and the subsequent atrial activation, it proves that the SVT is antidromic AVRT using an AV BT anterogradely, and excludes preexcited AVNRT.
- AES during the SVT that advances ventricular activation and does not affect VA interval excludes AVNRT and is diagnostic of antidromic AVRT.
- Exact atrial and ventricular capture by AES delivered when the AV junction is depolarized excludes AVNRT.

Entrainment of SVT by Atrial Pacing

- Failure of entrainment by atrial pacing to influence the VA interval during SVT excludes AVNRT.
- The presence of a fixed short VH interval during entrainment of the SVT with atrial pacing suggests antidromic AVRT, and makes AVNRT unlikely (but does not exclude AVNRT).

Entrainment of SVT by Ventricular Pacing

- Failure of entrainment by ventricular pacing to influence the VA interval during SVT excludes AVNRT.

Ventricular Pacing During NSR at the Tachycardia CL

- Pacing at the RV apex at TCL is performed, and the HA interval during RV pacing is compared with the HA interval during SVT. (It is important to verify that VA conduction occurred only over the same pathway as during SVT for this analysis to be valid.)
 - $HA_{\text{pacing}} > HA_{\text{SVT}}$ is diagnostic of AVNRT and excludes AVRT.
 - $HA_{\text{pacing}} \leq HA_{\text{SVT}}$ is diagnostic of AVRT and excludes AVNRT.
- VA block during RV apical pacing excludes AVRT.

AES, Atrial extrastimulus; AV, atrioventricular; AVNRT, atrioventricular nodal reentrant tachycardia; AVRT, atrioventricular reentrant tachycardia; BBB, bundle branch block; BT, bypass tract; CL, cycle length; HA, His bundle–atrial; ECG, electrocardiogram; HV, His bundle–ventricular; NSR, normal sinus rhythm; PCL, pacing cycle length; RV, right ventricle; SVT, supraventricular tachycardia; TCL, tachycardia cycle length; VA, ventriculoatrial; VES, ventricular extrastimulus; VH, ventricular–His bundle.

BOX 18.9 Electrophysiological Findings Indicating Presence of Multiple Atrioventricular Bypass Tracts

During Preexcited Rhythms (NSR, PACs, Spontaneous or Induced AF, RA, and LA Pacing)

- Changing anterograde delta wave (i.e., variations in preexcited QRS morphology). Atrial pacing from different sites (high RA and CS) may accentuate preexcitation over one BT and not the other, and help unmask the changes in the delta wave.
- Atypical pattern of preexcitation (i.e., does not conform to an expected QRS morphology for a given location)
- Changing anterograde delta wave following antiarrhythmic agents (e.g., amiodarone or class I agents) that may block one BT and not the other or following ablation of one BT

During Ventricular Pacing at Different CLs and From Multiple Pacing Sites

- Evidence of multiple routes of retrograde atrial activation:
- Changing P wave morphology or atrial activation sequence
- Multiple atrial breakthrough sites
- Changing VA interval
- Evidence of mismatch of site of anterograde preexcitation and site of retrograde atrial activation observed during ventricular pacing

During Orthodromic AVRT

- Evidence of multiple routes of retrograde atrial activation:
- Changing P wave morphology or atrial activation sequence
- Multiple atrial breakthrough sites
- Changing VA interval
- Failure to delay atrial activation at all sites with the development of BBB ipsilateral to the BT
- Evidence of multiple routes of anterograde ventricular activation:
- Intermittent anterograde fusion (preexcited) complexes
- Evidence of mismatch of site of anterograde preexcitation and site of retrograde atrial activation observed during orthodromic AVRT

During Antidromic AVRT

- Eccentric atrial activation sequence
- Varying degrees of anterograde fusion
- Changing VH interval without any change in the TCL or atrial activation sequence (suggesting that the HPS is not part of the reentrant circuit)
- Tachycardia CL during antidromic AVRT slower than orthodromic AVRT in the same patient (in absence of dual AVN pathways)
- Anterograde ventricular activation over posteroseptal BT
- The mere presence of antidromic AVRT

AF, Atrial fibrillation; AVN, atrioventricular node; AVRT, atrioventricular reentrant tachycardia; BBB, bundle branch block; BT, bypass tract; CL, cycle length; CS, coronary sinus; HPS, His-Purkinje system; LA, left atrium; NSR, normal sinus rhythm; PAC, premature atrial complex; RA, right atrium; TCL, tachycardia cycle length; VA, ventriculoatrial; VH, ventriculo-His.

Effects of Bundle Branch Block During Orthodromic Atrioventricular Reentrant Tachycardia

Prolongation of the TCL and, more importantly, the surface VA interval by more than 35 milliseconds following the development of BBB is diagnostic of AVRT using a free-wall BT ipsilateral to the BBB (LBBB with left-sided BT, and RBBB with right-sided BT). Superoparaseptal and posteroseptal BTs are associated with a lesser degree of prolongation of the VA interval (approximately 5 to 25 milliseconds) on the

Fig. 18.45 Identifying Multiple Bypass Tracts (BTs) in the Same Patient. The presence of multiple BTs is indicated by the mismatch of sites of anterograde preexcitation during normal sinus rhythm (the delta wave morphology is consistent with anterograde conduction over a right anterior BT) and site of retrograde atrial activation observed during ventricular pacing (the atrial activation sequence is consistent with ventriculoatrial conduction over a left lateral BT). CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; HRA, high right atrium; RVA, right ventricular apex.

development of BBB (RBBB with superoparaseptal BT, and LBBB with posteroseptal BT). In an analogous fashion, entrainment of the SVT by ventricular pacing that results in prolongation of the VA interval ($VA_{\text{pacing}} > VA_{\text{SVT}}$) suggests that the SVT is orthodromic AVRT mediated by an AV BT in the ventricle contralateral to the site of ventricular pacing.

Ventricular Entrainment During Orthodromic Atrioventricular Reentrant Tachycardia

During orthodromic AVRT, the corrected (PPI – TCL) difference following entrainment from the RV apex can help localize the BT used for retrograde conduction. The RV apical pacing site is closer to the reentrant circuit of orthodromic AVRT utilizing a right-sided BT than orthodromic AVRT utilizing a left-sided BT. Hence, as expected, the corrected (PPI – TCL) difference is shorter (less than 55 milliseconds) in patients with orthodromic AVRT with a right-sided BT when pacing the RV apex. Patients with left-sided BTs typically have a corrected (PPI – TCL) difference of more than 55 milliseconds.⁵¹

Furthermore, upon initiation of ventricular overdrive pacing from the RV apex during orthodromic AVRT, there is a “transitional zone” during which the paced QRS complexes show progressive fusion with

Fig. 18.46 Orthodromic Atrioventricular Reentrant Tachycardia With Multiple Routes of Retrograde Atrial Activation. The presence of multiple bypass tracts is indicated by the shift in retrograde atrial activation sequence (indicated by the *red and blue arrows*) during tachycardia. *CS_{dist}*, Distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *HRA*, high right atrium; *RVA*, right ventricular apex.

BOX 18.10 Electrophysiological Maneuvers for Localization of the Bypass Tract

Pacing From Multiple Atrial Sites

- Proximity to the BT atrial insertion is indicated by shortening of the P-delta interval during atrial pacing.

Preexcitation Index of VES From the RV

- A relative preexcitation index >90% suggests right-sided or septal BT.
- An absolute preexcitation index ≥ 75 msec suggests a left free-wall BT.
- An absolute preexcitation index <45 msec suggests a septal BT.
- An absolute preexcitation index of 45–75 msec is indeterminate.

Effects of BBB During Orthodromic AVRT

- Prolongation of the TCL and, more importantly, the surface VA interval by >35 msec following the development of BBB is diagnostic of AVRT using a free-wall BT ipsilateral to the BBB (LBBB with left-sided BT, and RBBB with right-sided BT).
- Superoparaseptal and posteroseptal BTs are associated with a lesser degree of prolongation of the VA interval (approximately 5–25 ms) on the development of BBB (RBBB with superoparaseptal BT, and LBBB with posteroseptal BT).

Ventricular Entrainment During Orthodromic AVRT From the RV Apex

- Corrected (PPI – TCL) difference <55 msec is consistent with a right-sided BT.
- Corrected (PPI – TCL) difference >55 msec is consistent with a left-sided BT.
- Resetting of ≥ 3 atrial beats (with fixed SA intervals) within the transitional zone suggests a right-sided BT.
- Resetting of only 1 or 2 atrial beats during the transitional zone suggests a left-sided BT.

Mapping Ventricular Activation During Preexcited Rhythm

- The site of earliest local ventricular activation (preceding the onset of the delta wave) along the tricuspid and mitral annuli identifies the BT ventricular insertion site.

Mapping Atrial Activation During Retrograde Bypass Tract Conduction

- The site of earliest local atrial activation along the tricuspid and mitral annuli during orthodromic AVRT or during ventricular pacing with retrograde conduction over the BT, identifies the BT atrial insertion site.
- The site of polarity reversal of the atrial unfiltered bipolar electrogram (with the electrodes oriented parallel to the axis of the annulus) during orthodromic AVRT or during ventricular pacing with retrograde conduction over the BT, identifies the BT atrial insertion site.

Mapping Bypass Tract Potential

- Recording a BT potential 10–30 ms before the onset of the delta wave (during anterograde preexcitation) or between the ventricular and atrial electrograms at the earliest site of retrograde atrial activation (during orthodromic AVRT or ventricular pacing) identifies the BT location.

Local AV or VA Interval

- When the BT crosses the AV groove perpendicularly, the site of the shortest local VA interval (during retrograde BT conduction) and the site of the shortest local AV interval (during anterograde BT conduction) can indicate the BT location and is often considered the optimal target for BT ablation.

AV, Atrioventricular; AVRT, atrioventricular reentrant tachycardia; BBB, bundle branch block; BT, bypass tract; LBBB, left bundle branch block; PPI, postpacing interval; RBBB, right bundle branch block; RV, right ventricle; SA, stimulus-to-atrial; TCL, tachycardia cycle length; VA, ventriculoatrial; VES, ventricular extrastimulus.

the SVT complexes, until stable QRS morphology is observed (either completely paced or constantly fused). The closer the BT location is to the RV apical pacing site, the earlier atrial resetting will occur during the transitional zone, and the greater the number of complexes that show advancement of atrial activation (as defined by acceleration of atrial

activation to the ventricular pacing rate with fixed SA intervals) during the transitional zone (Fig. 18.47). Right-sided BTs produce reset earlier than left-sided BTs, and resetting of at least three atrial beats (with fixed SA intervals) within the transitional zone was found to successfully identify right-sided BTs. Left-sided BTs allow atrial resetting later after

Fig. 18.47 Ventricular Entrainment During Orthodromic Atrioventricular Reentrant Tachycardia (AVRT) for Bypass Tract (BT) Localization. (A) Orthodromic AVRT over a right lateral BT with a tachycardia cycle length (TCL) of 339 milliseconds. Right ventricular apical (RVA) overdrive pacing is delivered at 320 milliseconds and the number of beats with a fixed stimulus-atrial (SA) interval within the transition zone (TZ) is 4 (the 4 last beats of the TZ). (B) Orthodromic AVRT using a right posteroseptal BT with a TCL of 316 milliseconds. RVA overdrive pacing is delivered at 300 milliseconds and the number of beats with a fixed SA interval within the TZ is two (the last two beats of the TZ). The star indicates the first paced beat with a fixed QRS-morphology, representing the last beat of the TZ. His d, Distal His bundle; His p, proximal His bundle; HRA, high right atrium. (From Akerström F, Pachón M, García-Fernández FJ, et al. Number of beats in the transition zone with fixed SA interval during right ventricular overdrive pacing determines accessory pathway location in orthodromic reentrant tachycardia. *Pacing Clin Electrophysiol.* 2015;39:21–27.)

starting ventricular overdrive pacing (due to the larger distance between the BT and the pacing site) and, hence, only one or two reset beats during the transitional zone would reveal atrial resetting. Septal BTs had numbers of reset complexes that overlapped with right- and left-sided BTs.⁵⁷

Earliest Ventricular Activation Site During Anterograde Bypass Tract Conduction

During ventricular preexcitation (preexcited sinus or atrial paced rhythm, or antidromic AVRT), the surface ECG lead with the earliest onset of the delta wave, preferably with a relatively sharp delineation of its onset, should be selected and used as the timing reference during mapping (eFig. 18.6). The site of earliest local ventricular activation (preceding the onset of the delta wave) along the tricuspid and mitral annuli identifies the BT ventricular insertion site.

Both bipolar and unipolar recordings on the ablation catheter should be used for mapping (Fig. 18.48). Bipolar electrograms display electrogram components and timing and may demonstrate a BT potential. The unfiltered (0.05 to 300 Hz) unipolar signal morphology should show a monophasic QS complex with a rapid negative deflection if the site was at the origin of impulse formation in the ventricle (i.e., BT

insertion site). Concordance of the timing of the onset of the bipolar electrogram with that of the unipolar electrogram (with the rapid downslope of the S wave of the unipolar QS complex coinciding with the initial peak of the bipolar signal) helps ensure that the tip electrode, which is the ablation electrode, is responsible for the early component of the bipolar electrogram. If only bipolar recordings are used, one does not know which of the two poles is responsible for the earliest component of the bipolar electrogram.

Earliest Atrial Activation Site During Retrograde Bypass Tract Conduction

During orthodromic AVRT or during ventricular pacing with retrograde conduction over the BT, the site of earliest atrial activation along the tricuspid and mitral annuli identifies the BT atrial insertion site. When mapping is performed during ventricular pacing, fusion of atrial activation, caused by simultaneous retrograde conduction over both the AVN and the BT, has to be considered because it can affect the accuracy of mapping. This can be an issue in the setting of septal BTs whereby the retrograde atrial activation sequence over the BT may not be very different from that over the AVN. Dissociation of retrograde conduction over the BT from that over the AVN is required in these situations, and

Fig. 18.48 Catheter Ablation (ABL) of a Left Anterolateral Bypass Tract (BT) During Anterograde Conduction. ABL is performed during preexcited atrial pacing. Preexcitation is observed during the first three complexes. The dashed line indicates the onset of the delta wave. Note the sharp negative deflection (QS morphology) in the unipolar recording. Also, note the concordance of the timing of the unipolar and bipolar electrograms (blue arrows), which precedes the onset of the delta wave by 10 to 15 milliseconds. A sharp potential (possible BT potential, red arrow) is recorded between the atrial and ventricular electrograms. RF application at this site successfully eliminated preexcitation (last two complexes). CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; HRA, high right atrium; RVA, right ventricular apex.

eFig. 18.6 Surface Electrocardiogram (ECG) and Intracardiac Recordings of Possible Ablation Site. On the left, with standard ECG recordings, the features of the ablation site electrograms suggest this would be a good ablation site (*green arrow*) because they occur well before the onset of the delta wave (*dashed line*). However, on the right, the very same complex is shown, but with increased gain on surface ECG leads as well as an addition of lead of V3 (showing sharp delineation of delta wave onset, *blue arrow*). Now, the dashed line that denotes the true onset of surface preexcitation reveals that the putative ablation site is not attractive (*red arrow*). *Abl_{dist}*, Ablation distal bipolar electrodes; *Abl_{prox}*, ablation proximal bipolar electrodes; *Abl_{uni}*, ablation distal unipolar electrode; *CS_{dist}*, distal coronary sinus; *CS_{mid}*, middle coronary sinus; *CS_{prox}*, proximal coronary sinus; *His_{dist}*, distal His bundle; *His_{mid}*, middle His bundle; *His_{prox}*, proximal His bundle; *HRA*, high right atrium; *RVA*, right ventricular apex.

can usually be achieved with ventricular stimulation from sites closer to the BT and with the use of AVN blockers (e.g., adenosine) to ensure preferential retrograde conduction over the BT.

As with ventricular mapping, both bipolar and unipolar recordings on the distal ablation electrode should be used for atrial mapping (Fig. 18.49). Determining what components of a complex ablation electrode recording is atrial versus ventricular can be facilitated by rapid burst ventricular pacing that does not conduct 1:1 retrogradely (Fig. 18.50) or by introduction of a VES that does not conduct retrogradely during fixed-rate ventricular pacing (Fig. 18.51). In either case, the principle is to compare the electrogram that is known to have no atrial component with the electrogram in question (with some atrial component), any difference being due to the contribution of the atrial electrogram.

Atrial Electrogram Polarity Reversal During Retrograde Bypass Tract Conduction

The morphology and amplitude of the bipolar electrograms are influenced by the orientation of the bipolar recording axis to the direction of propagation of the activation wavefront. Although the direction of wavefront propagation cannot be reliably inferred from the morphology of the bipolar signal, a change in morphology can be a useful finding,

and the unfiltered bipolar electrogram with the electrodes oriented parallel to the axis of the annulus can be used to localize the atrial insertion site of the BT.

During retrograde BT conduction (orthodromic AVRT or ventricular pacing), BT atrial insertion is identified as the site where the polarity of the atrial potential reverses. Because the site of BT atrial insertion is usually discrete, atrial activation propagates in two opposite directions along the annulus from the insertion site. As a result, an RS configuration electrogram will be present on one side of the BT, where the wavefront is propagating from the distal electrode toward the proximal electrode, and a QR morphology electrogram on the other side, where the wavefront is propagating from the proximal electrode toward the distal electrode.

This technique is typically used for localization of left free-wall BTs via the transeptal approach, which allows an electrode orientation parallel with atrial activation along the mitral annulus. As the ablation catheter is moved along the mitral annulus during retrograde BT conduction, the amplitude and polarity of the atrial electrogram are examined. With the tip electrode negative, and the catheter lying on the mitral annulus from anterior to posterior, an upright atrial electrogram indicates a catheter position anterior to the insertion site,

Fig. 18.49 Catheter Ablation (ABL) of a Left Lateral Bypass Tract (BT) During Retrograde Conduction. ABL is performed during ventricular pacing with atrial fusion (ventriculoatrial conduction occurring over both the BT and atrioventricular node [AVN]). The dashed line indicates the onset of the earliest atrial activation. Note the sharp negative deflection (QS morphology) in the unipolar recording. The timing of the unipolar electrogram coincides with the bipolar electrogram (blue arrows) and precedes the delta wave by 5 to 10 milliseconds. The atrial and ventricular electrograms merge, and the true morphology of the ventricular electrogram is unmasked after successful ablation (last two complexes). A sharp potential (possible BT potential, red arrow) is recorded between the two electrograms. After successful elimination of the BT function, atrial activation occurs exclusively over the AVN (last two complexes, green arrows). *CS_{dist}*, Distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *HRA*, high right atrium; *RVA*, right ventricular apex.

Fig. 18.50 Using Ventricular Pacing to Evaluate Ablation Site Electrogram Components. Burst ventricular pacing is shown at a rate that produces 2:1 retrograde conduction over the bypass tract (BT). This facilitates determination of what portion of the ablation site recording is atrial versus ventricular, because whatever is present in recordings on cycles during which retrograde conduction is present, but absent when retrograde conduction fails, is the atrial (or BT plus atrial) recording (red arrows). *Abl_{dist}*, Ablation distal bipolar electrodes; *Abl_{prox}*, ablation proximal bipolar electrodes; *Abl_{uni}*, ablation distal unipolar electrode; *CS_{dist}*, distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *His_{dist}*, distal His bundle; *His_{mid}*, middle His bundle; *His_{prox}*, proximal His bundle; *HRA*, high right atrium; *RVA*, right ventricular apex.

whereas a negative electrogram indicates positions posterior to the insertion site. When the bipole approaches and then passes directly over the atrial insertion site, the atrial electrogram becomes diminished in amplitude, isoelectric, and fractionated. As the catheter moves from one side of the insertion site to the other side, reversal of the atrial electrogram polarity is observed. This maneuver has a sensitivity of 97%, specificity of 46%, and positive predictive value of 75%. For BTs at other locations, mapping can be facilitated by using a multipolar catheter positioned in the CS or around the tricuspid annulus (e.g., Halo catheter); the site of the BT atrial insertion is enclosed between the two adjacent bipoles, demonstrating atrial electrogram polarity reversal.

Direct Recording of Bypass Tract Potential

The BT potential manifests as a sharp narrow spike on both unipolar and bipolar recordings 10 to 30 milliseconds before the onset of the delta wave during anterograde preexcitation or between the ventricular and atrial electrograms at the earliest site of retrograde atrial activation during orthodromic AVRT or ventricular pacing. The BT potential amplitude averages 0.5 to 1 mV at successful ablation sites (see Figs. 18.48 and 18.49). Similar electrical signals, however, can be a component of the atrial or ventricular electrogram, and proof that an electrical signal is actually a BT potential can be difficult, because it needs to be dissociated from the local atrial and ventricular electrograms.

During anterograde BT conduction (NSR or atrial pacing), dissociation of the anterograde BT potential from the ventricular potentials can be achieved by introduction of VES with progressively shorter coupling intervals. Dissociation of the BT potential from the local ventricular potential is confirmed when a late-coupled VES (occurring at the time of the anterograde BT potential) advances the ventricular electrogram without affecting the timing or morphology of the BT potential. Furthermore, dissociation of the BT potential from the local atrial potential is confirmed when an earlier VES advances the BT potential without affecting the timing or morphology of the atrial electrogram (Fig. 18.52).

A retrograde BT potential (during ventricular pacing or orthodromic AVRT) can be validated by introduction of progressively premature AES. A late-coupled AES can advance the timing of the local atrial potential without affecting the retrograde BT potential, providing evidence that the BT potential is not related to atrial activation. In addition, dissociation of the BT potential from the local ventricular potential is confirmed when an earlier AES advances the BT potential (i.e., anterogradely activate the BT) without affecting the timing or morphology of the local ventricular electrogram (Fig. 18.53).

However, these criteria for validation of BT potentials are often difficult to achieve. Therefore validation of BT potentials by programmed electrical stimulation is often not practical in clinical settings; instead, such a potential is called *possible* or *probable* BT potential.

Fig. 18.51 Using Ventricular Extrastimuli to Evaluate Ablation Site Electrogram Components. Determining what part of a complex ablation site recording is atrial or bypass tract (BT) is aided by introducing an extrastimulus (*S2*) during a fixed-rate drive, which fails to conduct retrogradely while drive complexes do conduct. The portion of the electrogram that is absent on this complex (*green arrow*), but present on others (*red arrows*), is the atrial (\pm BT) component. *Abl_{dist}*, Ablation distal bipolar electrodes; *Abl_{prox}*, ablation proximal bipolar electrodes; *Abl_{uni}*, ablation distal unipolar electrode; *CS_{dist}*, distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *His_{dist}*, distal His bundle; *His_{mid}*, middle His bundle; *His_{prox}*, proximal His bundle; *HRA*, high right atrium; *RVA*, right ventricular apex.

Targeting an isolated BT potential has been associated with the highest rate of ablation success. The usefulness of this criterion, however, has been limited by difficulty in locating or validating a BT potential in clinical practice. The difficulty in identifying the BT potential is often related to the oblique course of the BT. A ventricular or atrial wavefront propagating concurrently with the BT can overlap and mask the BT potential. Pacing from the site producing the shorter local VA or local AV intervals helps identify the BT potential in most of these cases.

Local Atrioventricular (or Ventriculoatrial) Interval

When the BT crosses the AV groove perpendicularly, the site of the shortest local VA interval (during retrograde BT conduction) and the site of the shortest local AV interval (during anterograde BT conduction) can indicate the BT location and is often considered the optimal target for BT ablation. However, the reliability of this criterion has been debated and can be misleading in the setting of oblique BTs. Short local VA intervals can occur at sites along the valve annulus distant from the BT because atrial and ventricular activation wavefronts can propagate circumferentially along the annulus, and the timing of local atrial and ventricular activation can be close to one another at multiple sites along the annulus (Fig. 18.54). Furthermore, with oblique BTs, the shortest local VA interval can be shifted away from the BT in the direction of the ventricular wavefront if the velocity of the ventricular wavefront along the annulus is less than the velocity of the atrial wavefront.

Similarly, the site of the shortest local AV interval can be shifted away from the BT in the direction of the atrial wavefront if the atrial wavefront is slower than the ventricular wavefront.

With an oblique course, the local VA and AV intervals vary by reversing the direction of the paced ventricular and atrial wavefronts, respectively. During ventricular pacing, a ventricular wavefront propagating from the direction of the ventricular end (concurrently with BT activation) produces an artificially short local VA interval (measured at the site of earliest retrograde atrial activation), because activation along the BT proceeds to the earliest atrial activation site simultaneously and in the same direction as the ventricular wavefront at the ventricular aspect of the AV groove. Contrariwise, a ventricular wavefront propagating in the opposite (countercurrent) direction produces a longer local VA interval because the ventricular wavefront must pass the site of earliest atrial activation before reaching the ventricular end of the BT (Fig. 18.55). This has important implications for localizing oblique AV BTs. With a concurrent wavefront, the ventricular potential can overlap the BT potential and atrial electrogram, masking the site of earliest atrial activation and BT potential. If the velocity of the ventricular wavefront along the annulus were slower than the BT and atrial wavefronts, the shortest local VA interval would be shifted away from the BT. A countercurrent wavefront should expose the atrial activation sequence and BT potential, but would result in a longer VA interval measured at the site of earliest retrograde atrial activation.

Fig. 18.52 Dissociation of Bypass Tract (BT) Potential From Local Atrial Potential. Surface electrocardiogram and intracardiac recordings evaluate possible BT potential. Fixed-rate atrial pacing is present on all three complexes shown. On the first complex, a blue arrow points to a possible BT potential following the sharp atrial potential (A). This same sharp atrial potential is seen at the same rate as atrial pacing on all three complexes. On the middle complex, a single ventricular extrastimulus is delivered almost simultaneously with the atrial drive stimulus (S). Here, the blue arrow shows that the putative BT potential does not follow the sharp atrial recording (red arrow indicates its absence), and thus is not part of the atrial electrogram. *Abl_{dist}*, Ablation distal bipolar electrodes; *Abl_{prox}*, ablation proximal bipolar electrodes; *Abl_{uni_d}*, ablation distal unipolar electrode; *CS_{dist}*, distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *His_{dist}*, distal His bundle; *His_{mid}*, middle His bundle; *His_{prox}*, proximal His bundle; *HRA*, high right atrium; *RVA*, right ventricular apex.

Similarly, during atrial pacing, a concurrent atrial wavefront would shorten the local AV interval (measured at the site of earliest ventricular activation) and could mask the BT potential and site of earliest ventricular activation. A countercurrent atrial wavefront should lengthen the local AV and expose the BT potential and ventricular activation sequence (see Fig. 18.55).

Reversing the paced ventricular or atrial wavefronts can increase the local VA or local AV interval, respectively, by at least 15 milliseconds in more than 85% of patients, which suggests that most BTs have an oblique course. The increase in the local VA or local AV intervals can facilitate identification of the BT potential. An anterograde or retrograde BT potential can be recorded in more than 85% of patients with oblique BTs, which is much more frequent than that with nonoblique BTs,

because fusion of the atrial, BT, and ventricular potentials may be expected with nonoblique BTs.

During retrograde BT conduction, the earliest atrial activation can be recorded 3 to 5 mm (or possibly more) from the actual BT insertion. Ablation is likely to be successful if the electrode is located 3 to 5 mm from the atrial insertion in the direction of the ventricular insertion and unsuccessful if located in the opposite direction. During anterograde BT conduction, ablation at a site recording earliest ventricular activation is likely to be successful, even if the electrode is located 3 to 5 mm from the ventricular end but in the direction of the atrial insertion and unsuccessful if located in the opposite direction. This explains the 40% ablation success for the criterion of local ventricular activation preceding the onset of the delta wave by less than

Fig. 18.53 Dissociation of Bypass Tract (BT) Potential From Local Ventricular Potential. Surface electrocardiogram and intracardiac recordings evaluate possible BT potential in the same patient as in Fig. 18.35. Fixed-rate ventricular pacing is shown in all three complexes, with a single atrial extrastimulus (AES) introduced during the middle complex. The blue arrow in the first complex points to a putative BT potential between ventricular (V) and atrial (A) electrograms. In the middle complex, the AES is timed such that the BT potential follows the atrial electrogram (blue arrow), and not the ventricular recording (red arrow). Thus it is not part of the ventricular electrogram. *Abl_{dist}*, Ablation distal bipolar electrodes; *Abl_{prox}*, ablation proximal bipolar electrodes; *Abl_{unip}*, ablation distal unipolar electrode; *CS_{dist}*, distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *His_{dist}*, distal His bundle; *His_{mid}*, middle His bundle; *His_{prox}*, proximal His bundle; *HRA*, high right atrium; *RVA*, right ventricular apex.

0 milliseconds during anterograde BT conduction, even though ventricular activation can usually be recorded as much as 30 milliseconds before the delta wave in right-sided BTs and 15 to 20 milliseconds in left-sided BTs.

ABLATION

Target of Ablation

The BT is the target of ablation. Although BT conduction can be eliminated by ablation anywhere between the atrial and ventricular ends, radiofrequency (RF) applications targeted to the atrial end (site of earliest atrial activation during retrograde BT conduction) or ventricular end

(site of earliest ventricular activation during anterograde BT conduction) occasionally fail, likely because of the broader dimension of BT at the insertion site compared to the annular aspect.

The best site of ablation of an AV BT is where it crosses the mitral or tricuspid annulus. Localization of the BT can be achieved with different mapping methods, as described earlier. Ablation should be performed at the same side of the annulus to the one being mapped (i.e., ablation on the atrial side during mapping of the atrial insertion site during retrograde BT conduction, and ablation on the ventricular side during mapping of the earliest ventricular activation during anterograde BT conduction). This is especially important for oblique BTs, whereby the earliest ventricular activation site during anterograde BT conduction

Fig. 18.54 Local Ventriculoatrial Interval for Bypass Tract Localization. Two ventricular paced complexes with retrograde conduction are shown. Ventricular (V) and atrial (A) recordings are as designated by lines. Of the recordings indicated, the earliest atrial electrogram is at the proximal coronary sinus (CS_{prox}), whereas the shortest local ventriculoatrial (VA) interval is far more distal in the coronary sinus recordings; in fact, in the distal coronary sinus (CS_{dist}), the VA interval is negative. Abl_{dist} , Ablation distal bipolar electrodes; Abl_{prox} , ablation proximal bipolar electrodes; Abl_{uni} , ablation distal unipolar electrode; His_{dist} , distal His bundle; His_{mid} , middle His bundle; His_{prox} , proximal His bundle; HRA , high right atrium; RVA , right ventricular apex.

from the atrial aspect of the annulus can be distant from the atrial insertion site of the BT; hence, ablation at the atrial aspect would not be successful.

Criteria of successful ablation sites during anterograde or retrograde activation mapping of BTs are presented in [Box 18.11](#) (see [Figs. 18.48](#) and [18.49](#)). The predictive accuracy of any single criterion is limited. Therefore selection of the optimal ablation target site should be guided by multiple criteria.

Ablation Technique: General Considerations

When preexcitation is present, ablation can be performed during NSR or, preferably, atrial pacing. For concealed BTs, RF energy is delivered during ventricular pacing, which usually allows for detection of an altered retrograde atrial activation sequence. RF energy delivery during AVRT is avoided if possible because of potential catheter dislodgment from its critical position upon interruption of BT conduction (and

thus abrupt tachycardia termination). This event can be associated with transient loss of conduction over the BT for a variable period of time without resulting in permanent damage to the BT due to premature interruption of the RF application. Occasionally, BT conduction can resume hours to days after the procedure; therefore one may not find a suitable target to complete the RF lesion if not addressed adequately during the initial attempt. Ablation during continuous pacing prevents this problem. For incessant orthodromic AVRT (e.g., PJRT), or when retrograde mapping during orthodromic AVRT is used to determine the optimal atrial ablation site, it is preferable to entrain the AVRT with ventricular pacing at a slightly shorter PCL so that block in the BT and termination of the SVT during RF energy delivery will be followed by ventricular pacing at a rate similar to that of the SVT, minimizing catheter movement. Also, the use of an electroanatomic mapping system can obviate this problem by tagging the initial site of ablation, allowing precise return to that site.

Fig. 18.55 Schematic Representation of Anterograde and Retrograde Activation of a Left Free-Wall Bypass Tract. The oblique course illustrates a change in electrogram timing with the reversal of the paced ventricular wavefront (A and B) and reversal of the paced atrial wavefront (C and D). AP, Accessory pathway potential; CS, coronary sinus; d, distal; LA, left atrium; LV, left ventricular; p, proximal. (From Otomo K, Gonzalez MD, Beckman KJ, et al. Reversing the direction of paced ventricular and atrial wavefronts reveals an oblique course in accessory AV pathways and improves localization for catheter ablation. *Circulation*. 2001;104:550.)

For most free-wall BTs, complete bidirectional block can be achieved with a conventional 4-mm-tip ablation catheter, using a power setting of 50 W and targeting a temperature of 60°C. If BT conduction block is transient, permanent BT block can usually be obtained with better and more consistent contact at the same site. It is rare that an 8-mm or irrigated-tip ablation catheter is necessary; failure of BT ablation is almost always a result of inadequate mapping or poor tissue contact and not inadequacy of the lesion size created by a 4-mm-tip standard ablation catheter. Nevertheless, irrigated-tip catheters can be helpful

when ablating in small branches of the CS because power delivery with a standard 4-mm electrode is limited because of less passive cooling in small vessels.

An electrode temperature of 55°C to 60°C should be sought. Transient loss of BT function is seen at roughly 50°C, and permanent loss of function occurs at 60°C. Therefore sites with favorable electrogram characteristics should not be abandoned until a temperature higher than 50°C to 55°C is reached. Conversely, repeated energy applications at the same location after achieving a temperature of 55°C or higher are unlikely to succeed.

Loss of BT conduction is expected within 1 to 6 seconds of RF application (once the target temperature and power delivery have been reached) for most successful lesions. If no effect is seen after 15 seconds of RF delivery, energy delivery should be discontinued because it is unlikely to be beneficial, and mapping criteria and catheter contact should be reexamined. If BT conduction is eliminated during the application, RF delivery should be continued for up to 60 seconds. Occasionally, BT conduction can be eliminated in one direction only (most typically loss of anterograde conduction with persistence of retrograde conduction). Thus testing for conduction in each direction is mandatory after what appears to be a successful RF application.

Transient interruption of BT conduction during RF delivery, with subsequent reappearance of conduction within seconds or minutes after energy delivery is completed, may be observed, and is more common with right than left free-wall BTs. In this setting, the use of multisite “insurance lesions” is discouraged, and the use of one or two ablation sites should be the goal, which requires careful mapping to achieve.

If BT function is not eliminated at a site with apparent favorable electrographic features, catheter contact with the tissue may be inadequate. Adequacy of catheter contact can be verified by evaluating the electrode temperature, catheter stability on fluoroscopy, electrogram stability, and ST elevation on the unipolar electrogram (Fig. 18.56). If the electrode temperature is consistently higher than 50°C with more than 25 W of energy delivered to the tissue during the RF application, good catheter contact is likely; however, if electrode temperature reaches more than 50°C but with very low power (less than 10 W), coagulum may have formed at the catheter tip. Also, catheter “shimmering” on fluoroscopy suggests poor contact. Similarly, changing electrographic amplitudes before or during ablation suggest inadequate catheter contact. Furthermore, ablation-related injury usually yields ST elevation on the unipolar electrogram; if absent, inadequate tissue heating is likely.

Endpoints of Ablation

Bypass Tract Bidirection Conduction Block

Confirmation of complete loss of BT function, and not just noninducibility of tachycardias, is essential. Confirmation of loss of anterograde BT function using AES and atrial pacing is achieved by demonstrating lack of preexcitation and marked prolongation of the local AV interval at the ablation site. Atrial stimulation should be performed at sites and rates that were associated with preexcitation before ablation. As noted, it is possible to have loss of anterograde conduction with persistence of retrograde conduction (less commonly the opposite). Therefore care must be taken to ensure bidirectional conduction block.

Confirmation of complete loss of retrograde BT function using VES and ventricular pacing is achieved by demonstrating concentric and decremental retrograde atrial activation, consistent with VA conduction over the AVN, VA dissociation, and/or marked prolongation of the local VA interval at the ablation site. Ventricular stimulation should be performed at sites and rates that were associated with retrograde VA conduction over the BT before ablation. Para-Hisian pacing and RV apical versus RV basilar pacing can also help confirm the absence of septal and paraseptal BTs (Figs. 18.28 and 18.30). Occasionally, AVN

BOX 18.11 Electrophysiological Criteria of Successful Bypass Tract Ablation Sites**Criteria of Successful Ablation Sites During Anterograde Activation Mapping**

- Stable catheter position, as confirmed fluoroscopically and by observing a stable electrogram (<10% change in amplitude in atrial and ventricular electrograms over 5–10 beats).
- Atrial electrogram amplitude >0.4 mV, or A/V ratio >0. Both atrial and ventricular electrogram components should be recorded from the ablation (tip) electrode. When ablating from the atrial aspect of the annulus, the atrial electrogram is usually equal to or larger than the ventricular electrogram. Sometimes, the two can merge and it may be difficult to determine whether both components are present. Rapid atrial or ventricular pacing resulting in block in the BT can help eliminate ventricular or atrial electrogram (respectively) so that the exact morphology of the other component can be visualized.
- Local AV interval on the ablation catheter is usually short (25–50 msec, except for previously damaged, slowly conducting, oblique, or epicardial BTs).
- The local ventricular electrogram on the ablation catheter should precede the onset of the delta wave on the ECG by a mean of 0–10 msec for left-sided BTs and 10–30 msec for right-sided BTs (the local ventricular electrogram is measured from the peak of the bipolar electrogram or the maximal dV/dt in the unipolar electrogram).
- QS (or, less preferably, rS) morphology of the unipolar electrogram. Right-sided BTs usually have unipolar recordings that show more pronounced (rapid and deeper) QS configuration than left-sided BTs.
- Continuous electrical activity (defined as isoelectric interval of <5 msec between ventricular and atrial electrograms).
- Presence of BT potential.

Criteria of Successful Ablation Sites During Retrograde Activation Mapping

- Stable catheter position, as confirmed fluoroscopically and by observing a stable electrogram (<10% change in amplitude in atrial and ventricular electrograms over 5–10 beats).
- Earliest local atrial activation timing.
- Local VA interval during retrograde activation of the BT is short (25–50 msec, except for previously damaged, slowly conducting, oblique, or epicardial BTs), usually resulting in inscription of the atrial electrogram on the ascending portion of the terminal ventricular electrogram. The “pseudo-disappearance” of the atrial electrogram within the terminal portion of the ventricular electrogram (forming a W sign) during orthodromic AVRT is a manifestation of an extremely short local VA interval, which correlates with successful ablation sites.
- Surface QRS to local atrial electrogram interval ≤70 msec (during orthodromic AVRT).
- The local VA interval remains constant regardless of the direction in which the ventricular wavefront engaging the BT is traveling (i.e., despite pacing from different ventricular sites). If one uses the ventricular approach to ablate a concealed BT, the ventricular insertion site can be identified as one that maintains a constant local VA interval, despite differences in direction of activation to the ventricular site.
- Continuous electrical activity (defined as isoelectric interval <5 msec between ventricular and atrial electrograms).
- Presence of BT potential.

AV, Atrium to ventricle; AVRT, atrioventricular reentrant tachycardia; BT, bypass tract; ECG, electrocardiogram; VA, ventriculoatrial.

conduction is so brisk that it is difficult to determine if a left-sided BT has been eliminated; in this case, pacing from the LV (either passing the ablation catheter through the mitral orifice and pacing LV endocardium, or advancing the CS catheter into a ventricular branch to pace) gives an advantage to conduction over a left-sided BT compared to the AVN.

Adenosine Testing

Administration of adenosine (starting dose 12 mg, 15 to 30 minutes after successful BT ablation) has been proposed to help unmask dormant BT conduction. Doses of adenosine are increased (in 6- to 12-mg increments) as needed to ensure adequate response in the form of AV block or sinus slowing. Then, atrial and ventricular programmed stimulation is performed to evaluate the presence of BT conduction. In a recent study, adenosine could induce transient anterograde and retrograde BT conduction (dormant conduction) after apparently successful BT ablation in 12% of patients. The mechanism of this phenomenon is thought to be secondary to membrane hyperpolarization of partially depolarized cardiac tissue after ablation. Dormant conduction was manifest during the bradycardia phase of adenosine effect. The presence of dormant BT conduction was associated with higher rates of repeat BT ablation, particularly in patients in whom dormant BT conduction was not successfully abolished during the initial procedure.⁵⁹

Ablation of Left Free-Wall Bypass Tracts**Anatomical Considerations**

The mitral annulus is an anatomically ill-defined structure that demarcates the hinge line of the mitral leaflets at the junctional zone that separates the LA and LV. The mitral annulus is not a rigid fibrous ring but pliable and dynamic, changing shape during the cardiac cycle. En

face, the mitral annulus resembles a kidney bean. When viewed in a 3-D perspective, the annulus has a nonplanar saddle shape, with elevated septal and lateral segments. The anterior flatter portion of the mitral annulus is continuous with the noncoronary and left coronary aortic cusps (the aortomitral continuity). Both annuli are anchored at two junctions: the left fibrous trigone (anchoring the anteromedial aspect of the mitral annulus to the base of the left coronary cusp) and the right fibrous trigone (formed by the triangular formation between the aortic valve and the medial parts of the tricuspid and mitral valves). Between the two trigones, a rigid and broad fibrous curtain (often referred to as the aortic curtain) extends across the anterior leaflet of the mitral valve and supports the aortic valve leaflets. The posterior part of the mitral annulus runs distal to the left and right fibrous trigones and includes the low points of the saddle close to the lateral and medial commissures and the posterior saddle horn. Compared to the anterior portion, the posterior mitral annulus is more loosely anchored to the surrounding tissue, allowing it to move freely with myocardial contraction and relaxation. The commissural diameter being larger than the anteroposterior diameter.⁶⁰

The aortic and mitral valvular orifices are fitted alongside each other (at the aortomitral continuity) within the elliptical ostium of the LV, with no ventricular muscle between. As a result, BTs are rarely found in the region of the aortomitral continuity. Left-sided BTs predominantly cross the free-wall portion of the mitral annulus.

Although the atrial insertion of the BT is typically discrete in size (1 to 3 mm) and close to the mitral annulus, the ventricular insertion site tends to ramify over the region of tissue and can be displaced a small distance away from the mitral annulus, toward the ventricular apex. The BT crosses the annulus on its epicardial aspect and may cross

Fig. 18.56 Effect of Ablation on Unipolar ST Segment. On the left ("Failed Site"), recordings during orthodromic atrioventricular reentrant tachycardia are shown following an unsuccessful ablation attempt. The distal ablation unipolar (Abl_{unip}) recording shows minimal, if any, ST segment shift in the ventricular recording (red arrow). On the right ("Successful Site"), a single complex of sinus rhythm is shown with significant ST elevation (blue arrow), indicating injury has occurred at that site. Abl_{dist} , Ablation distal bipolar electrodes; Abl_{prox} , ablation proximal bipolar electrodes; Abl_{unip} , ablation proximal unipolar electrode; CS_{dist} , distal coronary sinus; CS_{prox} , proximal coronary sinus; His_{dist} , distal His bundle; His_{mid} , middle His bundle; His_{prox} , proximal His bundle; HRA , high right atrium; RVA , right ventricular apex.

at variable depths within the epicardial fat pad. Most left free-wall BTs cross the mitral annulus obliquely, with the atrial insertion typically 4 to 30 mm proximal (posterior) to the more distal (anterior) ventricular insertion site (as mapped from within the CS).

Conduction at the insertion sites of the BT is markedly anisotropic because of almost horizontal orientation of the atrial and ventricular

fibers as they insert into the mitral annulus. In addition, the atrial fibers run parallel to the annulus, giving rise to rapid conduction away from the insertion site, parallel to the annulus, and slow conduction to the free-wall of the atrium, perpendicular to the annulus.

Importantly, while the CS is useful as a guide for mapping the mitral annulus in the left anterior oblique (LAO) fluoroscopy view, it has a

variable relationship to the mitral annulus (eFig. 18.7). The CS lies 2 cm superior to the mitral annulus as it empties into the RA. Anterolaterally, the CS frequently overrides the LV. Thus, depending on the distance from the ostium, the CS can lie above the mitral annulus and be associated with the LA, or can cross over the LV side of the mitral annulus. Furthermore, the CS is located more inferior to the mitral annulus on fluoroscopy in most patients. Therefore electrograms recorded from the CS can only provide gross estimates of the true atrial and ventricular insertion sites of the BT and can only be used to guide the ablation catheter to areas in which more detailed mapping needs to be performed.⁶¹

Technical Considerations

Transaortic (retrograde) approach. The right femoral artery is the most commonly used access for the transaortic approach. A long vascular sheath can provide added catheter stability, although with a possibly increased risk of thromboembolism. Anticoagulation is started before the LV is accessed to maintain the activated clotting time (ACT) between 250 and 300 seconds. The ablation catheter is advanced to the descending aorta and, in this position, a tight J curve is formed with the catheter tip before passage to the aortic root to minimize catheter manipulation in the arch. In the right anterior oblique (RAO) fluoroscopy view, the curved catheter is advanced through the aortic valve with the J curve opening to the right, so the catheter passes into the LV, oriented anterolaterally. The straight catheter tip must never be used to cross the aortic valve because of the risk of leaflet perforation. Once in the LV, and while maintaining a tight curve, the catheter is rotated counterclockwise and withdrawn in the LA as the tip turns posteriorly. By opening the J curve slightly, the tip can easily map the mitral annulus; clockwise torque moves the tip anteriorly (distally along the CS), and counterclockwise torque returns the tip posteriorly (proximally along the CS). Alternatively, after crossing the aortic valve, the catheter can be straightened and steered directly under the mitral annulus to the BT location or withdrawn in the LV outflow tract, rotated posteriorly with a slight curve, and then advanced under the posterior mitral annulus for left paraseptal or posterior BTs. When the ablation catheter is approximated along the mitral annulus, the catheter tip is simultaneously withdrawn and straightened slightly to slip under the annulus for fine manipulation. For left lateral and anterior BTs, extended-reach catheters may be required.

Catheter positions beneath the annulus between the ventricular myocardium and mitral leaflet are most stable for ablation of the BT ventricular insertion, but manipulation can be constrained by the chordae. Catheter positions above or along the annulus provide more freedom to map along the mitral annulus but are sometimes too unstable for successful energy delivery. Initial mapping is performed with the ablation electrode on the annulus. From this general area, the catheter is then positioned beneath the mitral annulus for more precise mapping. Catheter tip positions beneath the mitral annulus are suggested by proximity to the CS catheter, motion concomitant with the CS catheter, and an A/V electrogram ratio of less than 1.

Because the transaortic approach targets the ventricular insertion site of the BT, it is best suited for mapping anterograde BT activation (i.e., preexcitation). Mapping retrograde activation from the subannular position is more difficult than for anterograde mapping because of obscuration of the low-amplitude atrial electrogram following the large ventricular electrogram.

Although BT locations are commonly defined by mapping along the CS catheter, this only approximates localization of the subannular ablation site because of the oblique course of left free-wall BTs, displacement of the CS above the mitral annulus, variable basilar-apical ventricular insertion of the BT, and BT location beyond the distal CS electrode.

Transseptal approach. Transseptal and transaortic approaches are equally effective for ablation of left free-wall BTs. The transseptal approach is primarily used for mapping of the BT atrial insertion site during retrograde BT conduction (orthodromic AVRT or ventricular pacing), while ventricular mapping of manifest BTs (during preexcitation) using the transseptal approach is limited.

The transseptal approach has several advantages over the transaortic approach. The transseptal approach provides better access to far lateral and anterolateral BT locations, easier catheter maneuverability in the LA, and less risk of coronary injury. In addition, no arterial access is required with the transseptal approach, and vascular recovery is therefore shorter. However, the transseptal approach provides less catheter stability and is associated with a higher risk of cardiac perforation and air embolism. Furthermore, the transseptal approach entails higher cost if intracardiac echocardiography is used.

While mapping using the standard transseptal sheath, the ablation catheter's curvature can be modified according to BT location. For left posterior BTs, the catheter typically reaches the annulus without modifying the sheath position. The sheath is progressively withdrawn toward the RA for optimal catheter apposition at lateral BT locations, and it is almost entirely withdrawn toward the RA for anterior BTs. Alternatively, preformed or deflectable sheaths may be used. Ablation catheters with bidirectional asymmetric deflections can also be of value in some cases.

Once the ablation catheter is positioned on the mitral annulus in a 30-degree RAO view, mapping is performed in the LAO view. In the absence of preformed septal sheaths, gentle clockwise torque is needed to maintain the catheter on the posterior mitral annulus. No torque is needed for lateral positions. As the catheter is moved anteriorly, counterclockwise torque is necessary to keep the catheter tip on the annulus. In the anterior positions, the catheter tip can dislodge into the LA appendage or LV, and attention to intracardiac electrograms is necessary when mapping anterior regions, because the CS catheter rarely provides an accurate fluoroscopic reference in this setting. The goal is to maintain the catheter tip on the atrial aspect of the mitral annulus, so that the mitral annulus can be easily mapped by advancing and withdrawing the catheter, causing it to slide along the mitral annulus freely in parallel to the CS catheter. Advancing the catheter moves the tip posteriorly; withdrawing it moves the tip anteriorly. The ventricular aspect of the mitral annulus can be mapped by passing the catheter tip across the mitral valve and deflecting the tip toward the annulus.

The transseptal approach facilitates mapping of the atrial aspect of the mitral annulus. Catheter position on the atrial aspect of the annulus can be verified by recording a bipolar A/V electrogram amplitude ratio greater than 1, and a unipolar electrogram PR segment displacement from baseline without ST segment displacement. The stability of the catheter can be assessed by PR segment elevation (confirming good atrial tissue contact), consistent local electrographic amplitudes, and concordant motion of the CS and ablation catheters.

Because of the mobility of the ablation catheter and the electrode orientation parallel with atrial activation along the mitral annulus, a unique vectorial mapping technique is possible with the transseptal approach. As noted, using the unfiltered bipolar electrogram with the electrodes oriented parallel to the axis of the mitral annulus, the BT atrial insertion can be identified as the site at which the polarity of the atrial potential reverses.

Occasionally, ablation of far-left lateral BTs can result in apparent successful elimination of BT conduction, but shift to another, more septal pathway. Although the latter can happen, this finding is commonly due to ablation of tissue proximal to the BT insertion, such that CS activation must proceed from the (unablated) BT more distally and then activate the rest of the CS in a proximal-distal direction. Clues

eFig. 18.7 Anatomical Relationship Between the Coronary Sinus (CS) and Mitral Annulus. The distances between the CS and mitral annulus (MA) in the right anterior oblique projection (A) are 12.57 and 5.63 mm during systole at the proximal and distal CS, respectively. The distances between the CS and MA in the left anterior oblique projection (B) are 11.23 and 7.07 mm during systole at the proximal, middle, and distal CS, respectively. (From Kim J, Hwang G, Seo K, et al. Anatomical discrepancy between the coronary sinus and the mitral annulus by fluoroscopy. *Int J Arrhythm*. 2016;17:14–19.)

that this is the case include: (1) no change in the SVT CL (if ablation has been attempted in SVT); (2) no change in the ablation electrogram (because the BT has not been ablated); and (3) the earliest atrial activation was at the distal CS recordings, where ablation was attempted (eFig. 18.8). This can be prevented by mapping more distally than the site of earliest activation in CS recordings, and making certain the “earliest” site is surrounded by later ones.

Ablation of Right Free-Wall Bypass Tracts

Anatomical Considerations

Unique features of the tricuspid annulus and important anatomic differences as compared with the mitral annulus have often rendered ablation of right-sided BTs more challenging than that of left free-wall BTs. In addition, transient interruption of BT conduction during RF delivery, with subsequent resumption of conduction within seconds or minutes, and recurrence rates over the first few weeks after initially successful BT ablation, are more common with right-sided BTs compared with left-sided BTs.

A significantly larger endocardial area is present along the tricuspid ring because of the larger circumference compared with the mitral ring (approximately 12 vs. 10 cm). In addition, BTs can exist anywhere around the tricuspid annulus, whereas the mitral ring has an area of fibrous continuity with the noncoronary and left coronary aortic cusps (the aortomitral continuity) where BTs are rarely found. Despite these facts, right-sided BTs are much less common than left-sided BTs (12% vs. 59%).

In contrast to the mitral annulus, the tricuspid valve annulus is less well developed and frequently discontinuous. The tricuspid fibrous ring is often incomplete and has several gaps at which atrial and ventricular muscle fibers nearly abut. Right free-wall BTs can consist of thin strands crossing the epicardial aspect of the annulus (similar to left free-wall BTs) or pass subendocardially as relatively broad bands of tissue through the fibrous discontinuities. Furthermore, right free-wall BTs can insert into the myocardium (typically on the atrial side) several millimeters away from the fibrous annulus and have been associated with a higher prevalence of branching pathways.⁶²

Unlike the mitral valve, which attaches to its fibrous annulus at a right angle, the tricuspid valve attaches to its annulus at an acute angle oriented toward the RV, making it more difficult to wedge an ablation catheter underneath the tricuspid valve. In addition, unlike left free-wall AV BTs, which tend to pass close to the hinge line of the mitral valve, the AV groove between the RA and RV is much deeper than on the left side. The deep groove can allow the RA wall to fold over onto the RV wall, and the BT muscle bundles can cross at any depth. Hence, the right-sided BTs can be somewhat removed from the tricuspid annulus. In fact, atrial insertion of the BT can be as far as 1 cm away from the annulus in the folded-over atrial sac. The folded-over atrium and the bizarre angle required for mapping of the inferior and posterolateral aspect of the RA by a catheter passed through the RA from the inferior vena cava (IVC) can make it difficult to achieve a stable catheter position at the tricuspid annulus because of a tendency of the catheter to fall into the folded-over sac. Thus sometimes the superior vena cava (SVC) approach is required to allow full exploration of the folded-over atrial sac and the inferior-inferolateral positions around the tricuspid annulus. The standard IVC approach, however, is usually adequate to map the superior aspects of the tricuspid annulus. If the IVC approach is used, a guiding sheath can be especially helpful for better catheter stability and tissue contact. The use of a multipolar (Halo) catheter positioned around the tricuspid annulus can provide good regional localization to guide the ablation catheter.⁶³

Furthermore, closely adjacent but anatomically discrete sites of catheter ablation can be necessary to eliminate anterograde and retro-

grade BT conduction in up to 10% of patients—the incidence is highest (18.6%) with right free-wall BTs. The explanation for this phenomenon is not clear but probably relates to the complexity of fiber orientation, possibly branching over 1 to 2 cm along the annulus. This factor emphasizes the importance of identifying and targeting both the atrial and the ventricular BT insertion sites.

Right-sided AV BTs are associated with higher incidences of anatomic variations and congenital abnormalities along the tricuspid annulus. Ebstein anomaly is an abnormality of the tricuspid valve in which the septal and often the posterior leaflets are displaced a variable distance into the RV and the anterior leaflet is usually malformed, excessively large, and abnormally attached or adherent to the RV free wall. The true tricuspid annulus, on the other hand, is not anatomically displaced, but can be poorly developed, with extensive discontinuities of the fibrous architecture. Thus a portion of the RV is “atrialized” in that it is located on the atrial side of the tricuspid valve, and the remaining functional RV is small. The atrialized portion of the RV is morphologically and electrically ventricular but functionally atrial. Ebstein anomaly can be associated with other cardiac anomalies, including a patent foramen ovale, atrial and ventricular septal defects, and RV outflow tract obstruction.

Right-sided BTs have been reported in 10% to 30% of patients with Ebstein anomaly, and they are multiple in up to 50% of patients. The BTs bridge the true anatomical tricuspid annulus, regardless of where the valve is located. Ablation of these BTs can be challenging because the electrical signals recorded from the atrialized portion of the RV can be complex and fractionated. Furthermore, identification of the true AV groove, along which BTs are targeted, can be difficult. Coronary angiography or insertion of a thin multielectrode catheter in the right coronary artery can be necessary to help identify the true AV groove and guide ablation catheter positioning. In addition, electroanatomic activation mapping during NSR can help define the *electrical* AV junction (true tricuspid annulus), where annular atrial and ventricular electrograms are recorded. Ablation is usually accomplished at the true tricuspid annulus, above the displaced valve leaflet, although some patients may undergo successful ablation from the ventricular side of the tricuspid annulus (but still above the valve leaflet).

Technical Considerations

Characteristically, successful ablation sites for right-sided BTs display local AV intervals that are shorter than those for BTs elsewhere, local ventricular electrograms preceding the onset of the delta wave by an interval longer than that for BTs elsewhere (18 ± 10 milliseconds for right-sided BTs versus 0 ± 5 milliseconds for left-sided BTs), and the unipolar recording showing more pronounced (rapid and deeper) QS configurations (Fig. 18.57).

Most commonly, ablation of right-sided BTs is approached from the atrial aspect. The optimal site of ablation is the earliest atrial activation site during retrograde BT conduction (during orthodromic AVRT or ventricular pacing), preferably with a BT potential present. The earliest site of atrial activation is identified using a roving catheter or a multipolar (Halo) catheter along the tricuspid annulus. If mapping is performed during ventricular pacing, conduction over both the BT and AVN can occur, resulting in atrial fusion, which can interfere with localization of the BT. Ventricular pacing performed close to the BT ventricular insertion site can accentuate atrial activation over the BT.

Occasionally, the BT can be better approached from the ventricular side. Ventricular activation mapping is performed during preexcited NSR, atrial pacing, preexcited SVT, or antidromic AVRT. The site of the earliest ventricular activation during preexcitation, preferably with a BT potential present, would be the optimal site. The earliest onset of ventricular activation recorded on the ablation catheter (using unipolar or bipolar electrograms) should precede the onset of the delta wave by

eFig. 18.8 Apparent Shift of Atrial Activation During Ablation for Orthodromic Atrioventricular Reentrant Tachycardia (AVRT) Using a Left Lateral Bypass Tract (BT). On the first three cycles, the atrial activation sequence is distal-to-proximal in the coronary sinus (CS). In the middle, atrial activation sequence suddenly shifts to proximal-to-distal in the CS due to ablation near the distal CS recording, but proximal to the actual BT insertion site. Left atrial/CS conduction is interrupted along the CS. AVRT does not terminate and is in fact the same arrhythmia (tachycardia cycle length remains unchanged, and the interval from QRS onset [dashed line] to ablation recording [arrow] also remains unchanged). CS propagation continues distally from the ablation site to the septum (not illustrated), activating the CS between the ostium and BT location in the proximal-distal direction. *Abl_{dist}*, Ablation distal bipolar electrodes; *CS_{dist}*, distal coronary sinus; *CS_{mid}*, middle coronary sinus; *CS_{prox}*, proximal coronary sinus; *His_{dist}*, distal His bundle; *His_{mid}*, middle His bundle; *His_{prox}*, proximal His bundle; *HRA*, high right atrium; *RVA*, right ventricular apex.

Fig. 18.57 Differences in Mapping Site Electrogram Characteristics With Right Versus Left Lateral Anterogradely Conducting Bypass Tracts (BTs). Dotted lines denote delta wave onset in each panel; A and V are atrial and ventricular components of the ablation recording. At left is a right lateral BT; note the ventricular electrogram precedes the delta wave onset and the unipolar recording has a deep negative deflection, also before the delta wave. In contrast, with a left lateral BT (*right panel*), the ventricular recording in the distal bipole begins coincident with the delta wave onset and the unipolar recording is not as sharp and occurs after the delta wave onset. *Abl D*, Ablation distal bipolar electrodes; *Abl P*, ablation proximal bipolar electrodes; *Abl uni-d*, ablation distal unipolar electrode; *Abl uni-p*, ablation proximal unipolar electrode; *CS*, coronary sinus; *HIS D*, distal His bundle; *HIS M*, middle His bundle; *HIS P*, proximal His bundle; *HRA*, high right atrium; *RVA*, right ventricular apex.

at least 10 to 25 milliseconds. For concealed BTs, the ventricular insertion site cannot be determined by ventricular activation mapping because of the lack of preexcitation. In this setting, recording of a BT potential can be especially useful in guiding ablation.

The tricuspid annulus is usually mapped in the LAO fluoroscopy view. The right posterior, posterolateral, and lateral regions are usually best mapped from the IVC approach. The right anterior and anterolateral regions can also often be ablated using the IVC approach, but the SVC approach can offer more stable and better catheter-tissue contact in these areas. The catheter can be prolapsed across the tricuspid valve to help stabilize the tip on the tricuspid annulus. In the LAO view, the HB is located at about 1 o'clock and the CS at 5 o'clock; right free-wall BTs span from approximately 6 to 12 o'clock. Right anterior BTs are at the most superior aspect of the tricuspid annulus, right superoparaseptal BTs are located near the HB catheter, and right posterior free-wall BTs are located at the most posterior aspect of the tricuspid annulus, whereas right posteroseptal BTs are located near the CS.

Although the location of the mitral annulus is reasonably indicated by the CS catheter, the location of the tricuspid annulus is not as easily discerned because there is no analogous venous structure to mark with a catheter. Furthermore, because the mitral and tricuspid annuli are

not always in the same plane, the CS catheter is only a rough guide to the location of the tricuspid annulus in the RAO view. Attempts at providing an endocardial reference catheter along the tricuspid annulus have been made using a 20-pole Halo catheter. This approach has had limited success because the catheter often does not position directly on the AV groove. Introducing the Halo catheter through a preformed sheath can provide better catheter stability along the tricuspid annulus. Occasionally, a fine angioplasty wire can be passed into the right coronary artery to delineate the location of the tricuspid annulus. The latter approach, however, has not been widely adopted, possibly in part because of concerns of prolonged instrumentation of the right coronary artery during the procedure. Another approach is to create a three-dimensional electroanatomic map (EnSite-NavX; St. Jude Medical, St. Paul, MN, United States) of the right coronary artery. After right coronary artery angiography, a 2.3-Fr octapolar microcatheter (Cardima Inc., Fresno, CA, United States) is inserted in the right coronary artery. Mapping and acquisition of the bipolar electrograms recorded by the microcatheter are performed during anterograde or retrograde BT conduction. This map allows for early removal of the catheter from the coronary artery while continuously displaying electroanatomic information to assist with mapping of the BT.⁶⁴

To target the ventricular aspect of the tricuspid annulus, the catheter is introduced across the tricuspid valve and looped back on itself in the RV underneath the valve until a small atrial electrogram and a larger ventricular electrogram are recorded, confirming adequate proximity to the tricuspid annulus. A long sheath may be used to stabilize the body of the catheter and direct the catheter to several different locations along the tricuspid annulus.

Three-dimensional electroanatomic mapping can help ablation of right-sided BTs, and is especially useful in the presence of multiple BTs or complicated anatomy. An electroanatomic color-coded activation map along the tricuspid annulus can be constructed, either along the atrial side, during orthodromic AVRT or ventricular pacing, or along the ventricular side, during anterograde preexcitation. Sites of interest can be tagged for further reference, so that the ablation catheter can be returned to any of them with precision. Information with regard to catheter stability and movement can also be provided.⁶²

Ablation of Anteroseptal (Superoparaseptal) and Midseptal Bypass Tracts

Anatomical Considerations

The midseptum is the only true muscular septal area between the offset attachments of the mitral and tricuspid valves, and it corresponds roughly to the location of the triangle of Koch. The triangle of Koch constitutes the endocardial surface of the region of the lower RA septum. It is bordered anteriorly by the insertion of the septal leaflet of the tricuspid valve and posteriorly by the fibrous tendon of Todaro. The apex of the triangle is formed by the junction of these two boundaries. The base of the triangle is formed by the anteromedial edge of the CS os and is continuous with the sub-eustachian pouch (*see Figs. 17.1 and 9.2*).^{65,66} Of note, the interatrial sulcus is displaced to the far left of the inter-ventricular sulcus, and because the AV valves are not isoplanar (the attachment of the septal leaflet of the tricuspid valve into the most anterior part of the central fibrous body is displaced a few millimeters apically relative to the attachment of the septal leaflet of the mitral valve), the true septal part of the AV junction (the RA-LV sulcus) actually separates the inferomedial RA from the posterior superior process of the LV (the right side above the tricuspid valve while the left side is below the mitral valve). Hence, the triangle of Koch can be considered the RA side of the AV muscular septum.

The compact AVN is located beneath the RA endocardium at the apex of the triangle of Koch, anterior to the CS os and directly above

the insertion of the septal leaflet of the tricuspid valve, where the tendon of Todaro merges with the central fibrous body. Slightly more anteriorly and superiorly is where the HB penetrates the AV junction through the central fibrous body and the posterior aspect of the membranous AV septum.^{65,66}

BTs with an atrial insertion in the floor of the triangle of Koch, posteroinferior to the compact AVN and HB and above the anterior portion of the CS os, have been labeled as midseptal; these BTs are the only truly septal BTs; hence, they can be referred to simply as septal BTs.

The previously named anterosseptal and posteroseptal areas are not truly “septal” but are parts of the parietal AV junction that are anterior and posterior to the true septum, respectively. Anterosuperior to the AV septum and compact AVN and HB, the tricuspid annulus diverges laterally away from the membranous part of the septum to course along the supraventricular crest of the RV (crista supraventricularis). This muscular structure interposes between the attachments of the leaflets of the tricuspid and pulmonic valves in the roof of the RV. BTs in this area (at the apex of the triangle of Koch) are labeled anterosseptal, but they must be considered “superoparaseptal” right free-wall BTs because anatomically they do not belong to the septum. There is no atrial septum in the region anterior to the HB recording site; the aortic root separates the right and left atrial walls here.

BTs are classified as “superoparaseptal” if the BT potential and His potential are simultaneously recorded from the mapping catheter placed at the HB region. A “para-Hisian” BT (which accounts for only 1% to 2% of all BTs) is a superoparaseptal BT with intimate proximity to the HB and is defined when the location of its successful catheter ablation coincided with either the largest recordable His potential or a His potential greater than 0.1 mV.⁶⁷

Electrocardiographic Considerations

The surface ECG can be valuable in anticipating septal or paraseptal locations of the BT and planning the catheter ablation procedure. Right superoparaseptal (anterosseptal) and midseptal BTs typically exhibit positive delta waves in leads I, aVL, and V3 through V6. Delta wave polarity in leads V1 and V2 can vary. Because of their superior location, right superoparaseptal BTs are associated with positive delta waves in all inferior leads (II, III, and aVF). In contrast, the delta wave in midseptal BTs is positive in lead II, predominantly negative in lead III, and negative or isoelectric in lead aVF. The combination of a negative delta wave in lead V1 and R/S transition in leads V3 to V4 suggests right-sided midseptal BT, whereas a biphasic delta wave in lead V1 and earlier QRS transition (in leads V1 to V2) suggest a left-sided location of the midseptal BT.

The surface ECG can also help distinguish para-Hisian locations of the BT (which is associated with the highest risk of AV block during ablation) from other superoparaseptal or septal locations. The presence of a negative delta wave in leads V1 and V2 was found to carry high specificity (92%) but poor sensitivity (25%) to detect the ventricular insertion of BTs with a strict invasive definition of para-Hisian location. In addition, the sum of initial r-wave amplitudes in those precordial ECG leads of less than 0.5 mV could be a useful, adjunctive marker in the noninvasive identification of these BTs (sensitivity 85%; specificity 75.5%).⁶⁷

Technical Considerations

A superoparaseptal location of the BT is initially suggested when the BT potential and His potential are simultaneously recorded from the diagnostic EP catheter placed at the HB region.⁶⁷ AES or short bursts of atrial pacing can help distinguish BT potential from the His potential. Atrial impulses that block in the AVN but conduct over the BT results in fully preexcited QRS morphology preceded by the BT potential but

with concomitant loss of the His potential. On the other hand, atrial impulses that block in the BT result in loss of preexcitation and BT potential recording but preserve His potential recording.

The precise location of the BT is verified by mapping this space in a 30-degree LAO fluoroscopy view using the ablation catheter advanced via the IVC. The use of a long vascular sheath can help stabilize the catheter tip during mapping and ablation in the superoparaseptal region. Also, mapping via the SVC approach is sometimes necessary to optimize catheter position and contact. Not infrequently, catheter-induced mechanical trauma can cause conduction block in the BT, which can hinder BT mapping and ablation. Therefore careful catheter manipulation is warranted during mapping in the region of the BT.

The optimal site of ablation is one from which the atrial and ventricular electrograms are recorded in conjunction with a BT potential, but with no or only a tiny His potential (less than 0.1 mV). Preferably, the ventricular insertion site (with V/A electrogram amplitude ratio greater than 2) of the BT is targeted with ablation to minimize the risk of damage to the AVN (the HB is more resistant to ablation on the ventricular aspect, generally within a fibrous sheath at that location). Occasionally, ablation is required in the presence of a marked (greater than 0.1 mV) His potential recorded through the ablation catheter (i.e., true “para-Hisian” BTs). Ablation of these BTs from the aortic root has been described and can be an important option to consider in these challenging cases.^{68,69}

For midseptal BTs, successful ablation is achieved in an area bounded superiorly by the electrode recording the His potential, and posteroinferiorly by the CS os, as marked by the apex of curvature in the CS catheter. The optimal site of ablation for a right midseptal BT is one from which atrial and ventricular electrograms are recorded simultaneously with a BT potential in between. Ablation is first attempted from the right side. If it is ineffective or early recurrence occurs after termination of RF application, then the left-sided approach is attempted.

For manifest BTs, RF application is performed during NSR or atrial pacing, which helps monitor both BT and AVN-HB conduction during RF energy delivery. In the setting of concealed para-Hisian BTs, it is challenging to assess the success of RF application and monitor AV conduction simultaneously. When RF delivery is performed during ventricular pacing, monitoring the success of RF application is not possible because the retrograde atrial activation sequence during ventricular pacing can be similar with either BT or AVN conduction. Atrial pacing during RF delivery is preferable because it helps monitor AV conduction and override junctional rhythms that may occur during RF delivery; however, it is not helpful for assessing the efficacy of RF application because the BT conducts retrogradely only. RF delivery during orthodromic AVRT is another option; however, this will certainly have the potential for catheter dislodgment on SVT termination, and such dislodgment can endanger the AVN-HB. Moreover, application of RF energy during orthodromic AVRT will not allow monitoring of AV conduction. In this setting, monitoring of the mode of termination of orthodromic AVRT during RF delivery is essential. Termination of orthodromic AVRT with an atrial electrogram signifies potential damage to the anterograde limb of the SVT circuit (i.e., the AVN), and therefore RF delivery should be immediately stopped. On the other hand, termination of orthodromic AVRT with a ventricular electrogram suggests successful block in the retrograde limb of the SVT circuit (i.e., the BT), and therefore RF delivery should be continued, with careful monitoring of AV conduction during NSR following termination of the SVT. Another valuable option is RF delivery during atrial-entrained orthodromic AVRT with manifest atrial fusion. This technique enables continuous monitoring of effects of RF application on BT function and also obviates a sudden change in ventricular rate on termination of the SVT. In addition, this technique allows monitoring of AV conduction during

RF application once the orthodromic AVRT is terminated, and therefore reduces the risk of damage to the AVN-HB. During successful RF application, termination of orthodromic AVRT will be indicated by transformation from the tachycardia P wave morphology and atrial activation sequence into a fully paced atrial activation sequence at the same rate.

Ablation in the region of the triangle of Koch is associated with 2% to 10% incidence of AV block and, to reduce this risk, such BTs should be ablated with the catheter placed on the tricuspid annulus or on the ventricular side of the tricuspid annulus, preferably with the use of lower RF power. Titrated RF energy output can be used for true para-Hisian BTs, starting with 5 W, and increasing by 5 W every 10 seconds of energy application, up to a maximum of 40 W. For other superoparaseptal BTs, ablation can be started at 30 W, targeting a temperature of 50°C to 60°C.

During RF ablation within the triangle of Koch, the occurrence of junctional tachycardia is not uncommon and is associated with loss of preexcitation; this should not be misinterpreted as successful ablation leading to continuing RF energy delivery. Instead, overdrive atrial pacing should be performed to monitor AV conduction or RF application should be stopped and other sites sought (Fig. 18.58). RF application should be stopped after 10 to 15 seconds if no block in the BT is achieved to minimize potential damage to the AVN-HB.

To reduce the risk of AV block, RF delivery should be immediately discontinued when the following occur: (1) the impedance rises suddenly (greater than 10 Ω); (2) the PR interval (during NSR or atrial pacing) prolongs; (3) AV block develops; (4) retrograde conduction block is observed during junctional ectopy; or (5) fast junctional tachycardia (TCL less than 350 milliseconds) occurs, which may herald imminent heart block.

Cryoablation of Superoparaseptal and Midseptal Bypass Tracts

Cryothermal ablation of BTs in the superoparaseptal and midseptal areas, both at high risk of permanent AV block with RF ablation, is successful and extremely safe. Cryoablation may also be used to ablate selected cases of epicardial left-sided BTs within the CS, well beyond the middle cardiac vein, once attempts using the transseptal and

transaortic approaches have failed. The experience with cryoablation in unselected BTs, however, is more limited and less satisfactory; this is likely related to multiple factors, including the learning curve and the smaller size of the lesion produced by cryoablation. In addition, many of the features of cryothermal energy that distinguish it from RF energy, and which are optimal for septal ablation, are less important or even useless for ablation of BTs located elsewhere.⁷⁰

A 6-mm-tip or 8-mm-tip cryocatheter is usually used. Not infrequently, because of the limited maneuverability and the wide distal electrode spacing of the cryocatheter (which can displace the geometric center point of the measuring bipole and greatly decreases precision), mapping of the target BT ablation site may need to be performed using a steerable quadripolar EP catheter with 2–5–2-mm distal electrode spacing prior to cryoablation.⁷¹

Cryomapping. Cryomapping, or ice mapping, is designed to verify that ablation at the chosen site will have the desired effect (i.e., block in the BT) and to ensure the absence of complications (i.e., AV block). Cryomapping is performed at -30°C in the selected site. At this temperature, the lesion is reversible (for up to 60 seconds) and the catheter is “stuck” to the endocardium in an ice ball that includes the tip of the catheter (cryoadherence). This permits programmed electrical stimulation to test the disappearance of BT conduction during ongoing ablation and also allows ablation to be performed during AVRT without the risk of catheter dislodgment on tachycardia termination. In the cryomapping mode, the temperature is not allowed to drop below -30°C , and the time of application is limited to 60 seconds. Formation of an ice ball at the catheter tip and adherence to the underlying myocardium are signaled by the appearance of electrical noise recorded from the ablation catheter’s distal bipole.

In patients with manifest preexcitation, cryomapping may be performed during NSR or atrial pacing (to monitor for loss of delta waves), during ventricular pacing (to monitor retrograde BT block), or during AVRT (to monitor tachycardia termination). For concealed BTs, cryomapping is preferably performed either during orthodromic AVRT or during ventricular pacing. Once an ice ball is formed, programmed electrical stimulation is repeated to verify that the BT has been blocked.

Fig. 18.58 Junctional Tachycardia During Radiofrequency (RF) Ablation of a Superoparaseptal Bypass Tract. The first few complexes demonstrate normal sinus rhythm with preexcitation. A few seconds after starting RF energy delivery, junctional tachycardia develops, with loss of preexcitation. This prompted immediate termination of RF application, after which preexcitation resumed. *ABL_{dist}*, Ablation distal bipolar electrodes; *CS_{dist}*, distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *HRA*, high right atrium; *RVA*, right ventricular apex.

If cryomapping does not produce BT conduction block after 10 to 30 seconds of freezing or results in detrimental effects on AV conduction, cryomapping is interrupted and, after a few seconds, allowing the catheter to thaw and become dislodged from the tissue, the catheter can be moved to a different site and cryomapping repeated. Alternatively, if the test application is unsuccessful but mapping findings are very favorable, after rewarming, further 30-second applications are tested, decreasing the temperature by 10°C for every step of the application, up to the last application at -70°C. This is because the amount of cryothermal energy required for permanent ablation is individualized, ranging from an application of -40°C for 40 seconds to one of -75°C for 480 seconds; limiting test applications to only -30°C can limit the applicability of cryoablation for these patients. In addition, the use of cryothermal energy at temperatures lower than -30°C should be considered safer than RF energy at these critical sites.

Cryoablation. When sites of successful cryomapping are identified by demonstrating BT conduction block with no modification of the normal AVN-HB conduction, the cryoablation mode is activated, in which a target temperature below about -75°C is sought (a temperature of -75°C to -80°C is generally achieved). The application is then continued for up to 480 seconds, creating an irreversible lesion. If the catheter tip is in close contact with the endocardium, a prompt drop in catheter tip temperature should be seen as soon as the cryoablation mode is activated. A slow decline in temperature or very high flow rates of refrigerant during ablation suggests poor catheter tip-tissue contact and, in such a case, cryoablation is interrupted and the catheter is repositioned. Additional cryoablation “bonus” applications (usually two to three freeze-thaw-freeze cycles) may be applied to consolidate the lesion formation and improve long-term success rates.

Advantages of cryoablation. Cryoablation has several distinct advantages. First, “cryomapping” allows creation of “test lesions,” in which ablation target sites are cooled to a temperature that reversibly and temporarily halts local electrical activity. This enables valuation of the success and safety of the cryotherapy, and untoward effects caused by cryotherapy can be detected and reversed by interruption of cryotherapy before inducing permanent tissue damage. This is of particular value when ablation is performed in the close vicinity of the compact AVN or HB. Second, cryoadherence enhances catheter stability during ablation. This facilitates creating small, discrete cryolesions, which helps avoid damage to adjacent structures. Also, cryoablation may be performed during SVT without the concern of catheter dislodgement upon tachycardia termination.

On the other hand, the cryocatheter is not yet as steerable as the conventional RF catheter. Catheter stiffness and limited maneuverability can limit proper positioning of the catheter tip and potentially result in tissue trauma and transient mechanical AV or BT block. Furthermore, the large electrode spacing decreases the specificity of mapping of the BT. These limitations can potentially be overcome by the use of an electroanatomic mapping system and a conventional EP catheter with 2-mm spacing for mapping of the precise BT location before targeting that site with cryoablation.⁷¹

Outcome of cryoablation. In recent series, the acute success rate of cryoablation of BTs in the superoparaseptal and midseptal regions exceeded 90% (range, 60% to 100%). However, recurrence rates after initially successful cryoablation remain high (occurring in up to 20% of patients), and overall success rates have been lower than those with RF ablation of BTs. Nevertheless, whereas RF ablation of some superoparaseptal and midseptal BTs may otherwise be abandoned (in up to 17% of patients) because of a prohibitive risk of AV block, cryoablation is a viable, and often successful, option to eliminate those BTs. Many patients often prefer a strategy to minimize the risk of procedural AV block even when associated with a lower rate of procedural success.

Although transient modifications of the normal AV conduction can be observed during cooling, no permanent modifications have been observed. RBBB has occurred on occasion, but inadvertent permanent AV block has yet to be reported. In fact, immediate discontinuation of cryothermal energy application at any temperature on observation of modification of AVN conduction results in return to baseline conditions shortly afterward.⁷¹⁻⁷³

Ablation of Posteroseptal (Inferoparaseptal) Bypass Tracts

Anatomical Considerations

The posteroseptal region corresponds to a complex anatomic region where the four cardiac chambers reach their maximal proximity posteriorly (i.e., the crux), and incorporates the converging segments of the AV rings as well as the CS with its proximal branches. The posteroseptal region spans the area between the central fibrous body (superiorly), the interventricular septum (anteriorly), the right posterior paraseptal region (right lateral border), and the left posterior paraseptal region (left lateral border). Posteroseptal BTs can be located in a relatively wide area either at an epicardial site around the proximal CS or the middle cardiac vein or at an endocardial site along the tricuspid annulus in the immediate vicinity of the CS os, or along the posteromedial ventricular aspect of the mitral annulus. Because the posteroseptal region is actually posterior to the septum and not a septal structure, posteroseptal BTs are more appropriately referred to as right- or left-sided “inferoparaseptal” or “posterior paraseptal” BTs.

Because the interatrial sulcus is displaced to the far left of the interventricular sulcus, and because the AV valves are not isoplanar (the tricuspid annulus is displaced apically 5 to 10 mm in relation to the mitral annulus), the true septal part of the AV junction (the RA to LV sulcus) actually separates the inferomedial RA from the posterior superior process of the LV. The undersurface of the CS is about 1 cm above the mitral annulus. The CS os abuts the superior margin of the RA-to-LV sulcus and the paraseptal mitral annulus in the pyramidal space, providing an access for BT ablation. The right margin of the posteroseptal space includes the area surrounding the CS os and the inferior portion of the triangle of Koch. The left margin (the junction of the posterior septum and left free wall) lies as far as 2 to 3 cm from the CS os. The epicardial dimension of the posteroseptal space at the level of the valve annuli extends a mean of 3.4 ± 0.5 cm. BTs can be located anywhere within this relatively large space or in the adjacent right or left free walls. BTs located close to the edges of the septum can be ablated from the adjacent atrial or ventricular cavity, but BTs located deep within the posteroseptal space or near the epicardial aspect require ablation from within the CS or cardiac veins. BTs located in the proximal 1.5 cm of the CS are almost always in the posterior septal region. Those located between 1.5 and 3 cm from the CS os can be in the left free-wall or posterior septal region, and those located more than 3 cm from the CS os are almost invariably in the left free wall.

Most posteroseptal BTs are believed to be RA-to-LV BTs, with the ventricular insertion attaching onto the posterior superior process of the LV, but some posteroseptal BTs are considered to be left paraseptal (connecting the LA to the LV) or right paraseptal (connecting the RA to the RV). Up to 20% of posteroseptal BTs connect the myocardial coat of the CS (which is connected anatomically and electrically to both the RA and LA) to the LV.⁷⁴⁻⁷⁶

Electrocardiographic Considerations

Prediction of the site of successful ablation of posteroseptal BTs into either the right or the left heart has been attempted by analysis of the preexcitation pattern on the surface ECG. In addition to the obvious limitation of the surface ECG in the case of concealed BTs (47.5% in

a recent report), reports on the accuracy of surface ECG features to differentiate BTs associated with the three compartments of the inferior paraseptal space have been conflicting. Furthermore, although ECG characteristics of ventricular preexcitation can potentially predict the ventricular insertion site of the BT, the ability to predict the successful approach to BT ablation remains limited.

Previous reports found that, in patients with preexcitation, a negative delta wave polarity in lead V1 and positive polarity in lead V2 favors right-sided localization of a posteroseptal BT, whereas left posteroseptal BTs were associated with biphasic or positive delta wave polarity in leads V1 and V2. Recent reports, however, have questioned the predictive value of such a criterion. The vast majority of posteroseptal BTs can be successfully ablated at the tricuspid annulus or within the proximal CS, although the delta wave polarity on the ECG suggests a left ventricular origin. This phenomenon can be explained by the fact that many posteroseptal BTs are “RA-to-LV” fibers and an RA approach for ablation would suffice even though the delta wave polarity in lead V1 is suggestive of left posteroseptal BTs.^{74–76}

On the other hand, the R/S ratio in lead V1 was found to be an accurate ECG parameter to predict the site of successful ablation of posteroseptal BTs. This finding might be related to the observation that the ventricular insertion of “RA-to-LV” posteroseptal BTs attaches onto the posterosuperior process of the LV, resulting in earlier activation of the posterobasal LV with positive delta wave and predominantly negative QRS morphology (R/S ratio less than 1) in lead V1. In contrast, the ventricular insertion of “LA-to-LV” BTs attaches to the posteromedial aspect of the mitral annulus, resulting in a positive delta wave and a predominantly positive QRS morphology (R/S ratio greater than 1) in lead V1.⁷⁵

Posteroseptal BTs typically display deeply negative delta waves in lead III. Lead aVF is also negative in right posteroseptal BTs, but less commonly negative in left posteroseptal BTs. A steeply negative delta wave in lead II is a specific indicator for epicardial posteroseptal BTs (typically requiring ablation from within the coronary venous system).

Technical Considerations

Ablation of posteroseptal BTs is usually more difficult than other BT locations because of the complexity of the anatomical structures involved. Mapping and ablation can be required at either the mitral or the tricuspid annulus, or inside the CS or its proximal branches. Therefore the ability to discriminate BTs amenable to ablation from the right side (on the tricuspid ring or inside the coronary venous system) from those

requiring ablation on the mitral annulus can potentially have great impact on procedure outcome and safety by reducing procedural and fluoroscopy times, reducing the number of unsuccessful RF applications, and avoiding unnecessary LA access and its potential complications.^{74,75}

In addition to the ECG criteria discussed above, invasive EP findings have been used to predict the successful ablation site of manifest or concealed posteroseptal BTs (Table 18.2; Fig. 18.59). The response of the VA interval during orthodromic AVRT to the development of BBB has been suggested to help distinguish between right and left posteroseptal BTs. Prolongation of the surface VA interval in response to BBB by 10 to 30 milliseconds compared to that with normal QRS predicts the ventricular insertion of the posteroseptal BT in the ventricle ipsilateral to the side of BBB. However, the utility of this observation in predicting the successful approach to ablation is limited.⁷⁴

Measurement of the Δ VA interval during orthodromic AVRT (the difference in VA intervals measured at the HB catheter and at the site of earliest atrial activation in the CS) was found to be useful for predicting the successful approach. A Δ VA interval of 25 milliseconds or more suggests a left endocardial BT, whereas a Δ VA interval less than 25 milliseconds favors a right endocardial BT. This suggests that atrial activation is relatively early in the HB region during retrograde conduction through both right endocardial and CS-associated BTs, compared with left endocardial BTs.⁷⁴

Furthermore, a previous report found that a VA interval less than 50 milliseconds recorded at the left posteroseptal region during RV pacing identified 71% of patients with left posteroseptal BTs, with 100% specificity. In patients with a VA interval greater than 50 milliseconds, a difference in the VA intervals of less than 20 milliseconds recorded at the HB region and at the left posteroseptal region during RV pacing predicted right posteroseptal BT with a sensitivity of 97%, a specificity of 85%, and a positive predictive value of 91%.

PJRT is usually caused by a slowly conducting BT, commonly located in the posteroseptal region. Although the mere presence of a long-RP orthodromic AVRT has been suggested to favor a right endocardial BT, in 50% of cases, such BTs can be located in the left posterior or free wall (greater than 4 cm inside the CS). In the remaining 50%, the BT is located between the base of the pyramidal space formed by the points of pericardial deflection that contact the posterior RA and LA. None have been reported in the anteroseptal region.⁷⁴

An earliest atrial activation during orthodromic AVRT in the middle CS favors a left endocardial ablation site. However, recent studies found that a large proportion (more than one-third) of patients with an

Prediction of successful ablation on concealed posteroseptal accessory pathways by a novel algorithm using baseline electrophysiological parameters. *Circulation*. 1996;93:982–991.)

earliest activation site at or distal to the mid-CS required ablation inside the CS after a failed left endocardial approach, and 35% of all BTs ablated from the right side produced such an eccentric retrograde atrial activation. Therefore the ability of the site of earliest atrial activation during AVRT to predict the successful ablation approach seems very limited, mainly because CS-associated BTs can produce a very much eccentric retrograde atrial activation sequence.⁷⁴

Careful analysis of CS electrograms recorded by a catheter placed inside the CS can help distinguish between left and right posteroseptal BTs. “Atrial” electrograms recorded from inside the proximal CS originate not only from LA myocardium, but also from activation of the CS myocardial coat. This results in “fragmented” or double potentials, with a low-amplitude, blunt “far-field” LA component and a larger, sharp “near-field” signal from the CS musculature. The sequence of LA and CS myocardial coat activation at the earliest “atrial” electrograms in the CS recorded during retrograde BT conduction can guide mapping of these BTs into right- or left-sided compartments of the posteroseptal space. An activation wavefront traveling from the posteroseptal RA toward the left (e.g., by pacing posterior to the CS os) will first activate the muscle coat covering the proximal CS, producing a large, sharp

signal recorded by the electrodes inside the CS. Discrete connections of the CS musculature with the LA will activate the LA myocardium, producing a lower-amplitude, blunt, “far-field” signal on the CS electrodes. Thus two-component “fragmented” or double potentials will be recorded in the proximal CS, with the sharp component preceding the blunt signal (sharp/blunt sequence). The same sequence (sharp/blunt) of potentials is expected to happen when a retrogradely conducting right-sided “endocardial” BT first activates RA myocardium and when a BT inserts directly into the CS musculature (as is the case with epicardial CS-associated BTs). In contrast, when pacing is performed from the lateral LA, the sequence is the opposite (blunt/sharp), with CS musculature activation following activation of LA myocardium. This sequence should be produced if a BT connects to LA myocardium (i.e., left-sided “endocardial” AV BTs), the first signal recorded in the CS being a “far-field” potential followed by later activation of the CS musculature resulting in a blunt/sharp sequence of potentials. Different conduction velocities of LA myocardium and CS musculature can cause the sequence of potentials to change farther away from the insertion site of the BT, explaining the importance of analyzing the electrograms recorded at the earliest site. The recording of double potentials inside the CS has been found to be especially common during retrograde conduction through posteroseptal BTs.⁷⁴

Generally, a right-sided endocardial approach is initially adopted for mapping and ablation of BTs in the posteroseptal region. The posteroseptal tricuspid annulus, including the CS os and its most proximal part, and inferomedial RA are carefully mapped. If the ablation site fails or no appropriate ablation site can be obtained, the left posteroseptal area is mapped (with a transaortic or transeptal approach, as described for left-sided BTs). A primary left-sided approach may also be considered if multiple ECG and EP features suggest a left-sided location of the BT. If endocardial mapping fails, an epicardial approach via the CS is then considered (see later discussion).

Ablation of Epicardial Bypass Tracts

Anatomical Considerations

Epicardial BTs can be found at any location, but are most common in the posteroseptal and left posterior regions. Epicardial BTs account for 4% of left-sided BT ablation cases and 10% of those in patients referred after a failed ablation attempt.⁷⁷

Embryologically, the CS develops from the sinus venosus, together with the smooth part of the RA. As a remnant of sinus venosus musculature, a cuff of striated muscle covers the proximal CS, continuous with RA myocardium at the CS os. The CS muscle coat extends for 25 to 51 mm from the CS os and may extend for several millimeters over the necks of the middle cardiac vein and posterior coronary vein. Although this muscle coat is usually separated from the LA by adipose tissue, broad and extensive muscular strands frequently bridge this separation, producing electrical continuity between the CS musculature and the LA. These myocardial sleeves or cords, however, do not usually extend into the ventricular myocardium. In variations, an AV BT (referred to as an “epicardial” BT) is formed by a connection between a sleeve-like extension of the CS myocardial coat (along the middle cardiac vein, posterior cardiac vein, or another coronary vein) and the epicardial surface of the LV myocardium (CS-ventricular BT).⁷⁸ In some cases, the muscle creating this connection is found in the neck of a CS diverticulum, usually arising within the proximal 1.5 cm of the CS and before the middle cardiac vein. The prevalence of CS-associated epicardial BTs is approximately 22% to 36% among patients with posteroseptal or left posterior BTs, and is up to 47% among patients with a previous failed ablation attempt. This highlights the difficulty of localizing these BTs.⁷⁴

Other types of unusual BTs that cannot be ablated with a standard endocardial approach at the annulus have been described. These include

BTs that connect an atrial appendage to its respective ventricle, which can be successfully ablated using a transcutaneous pericardial approach or endocardial ablation over a large area; ablation at the valve annulus is uniformly unsuccessful in these cases. Another example is BTs closely associated with the ligament of Marshall, which can be ablated by targeting this ligament.⁷⁹

Electrocardiographic Considerations

ECG predictors of epicardial posteroseptal BTs include the following: (1) steep negative delta wave in lead II; (2) steep positive delta wave in lead aVR; and (3) deep S wave in lead V6. A negative delta wave in lead II has the highest sensitivity and a positive delta in lead aVR has the highest specificity for prediction of the presence of epicardial (i.e., requiring ablation within the CS and its branches) versus endocardial posteroseptal BTs.⁷⁵

Technical Considerations

An epicardial location of the BT is suggested when the earliest site of endocardial ventricular activation does not precede the onset of the delta wave, and when a very large BT potential can be easily recorded on the CS electrodes. During anterograde conduction over a CS-ventricular BT, endocardial mapping of the RV and LV identifies far-field activation (unipolar potential has a wide initial R wave), with the earliest far-field ventricular potential recorded 1 to 3 cm apical to the tricuspid and mitral annuli. At those sites, the local endocardial ventricular activation (as indicated by a rapid downstroke on the unfiltered unipolar electrogram) is recorded late (greater than 15 milliseconds after the onset of the far-field ventricular potential), reflecting ventricular activation from epicardium to endocardium.

On the other hand, mapping within the CS during anterograde conduction over a CS-ventricular BT reveals the earliest ventricular activation, usually recorded from the branch of the CS containing the myocardial extension. At this location, the local ventricular activation is preceded by a high-frequency potential (similar to an anterograde BT potential) generated by activation of the CS myocardium extending along the venous branch (CS myocardial extension potential).

During retrograde conduction over a CS-ventricular BT, the CS muscular coat is activated prior to the LA myocardium, and the high-frequency component generated by the CS myocardial extension (similar to a retrograde BT potential) precedes the low-frequency component generated by activation of the LA. In contrast, with left-sided “endocardial” BTs, the impulse activates the LA before the CS and the low-frequency, far-field signal from the LA will precede the sharp CS component.⁷⁴

Elimination of CS-ventricular BT requires ablation within the coronary venous system. Ablation of these BTs from the endocardial aspect at the mitral annulus often fails because of the extensive connections between the CS myocardial coat and the LA and the absence of a clear endocardial location for the ventricular insertion of the CS-ventricular BT. Generally, ablation is ineffective when attempted endocardially targeting the site of earliest anterograde ventricular activation or targeting the site of earliest retrograde atrial activation. Of note, endocardial ablation at the site of earliest retrograde atrial activation often produces only a shift in the site of earliest atrial activation (mimicking multiple BTs) because ablation usually results in interruption of one of the multiple connections of the CS myocardial coat to the atria.⁷⁴

The CS provides a useful route for mapping and ablation of epicardial BTs. CS-ventricular BTs are generally ablatable on the floor of the CS at the orifice of a venous branch or within a CS diverticulum. The middle (or “posterior interventricular”) cardiac vein is a well-established site for posterior epicardial BTs, and is useful for approaching AV BTs located in the inferior pyramidal space. This vein courses with the posterior descending coronary artery in the posterior interventricular groove

and enters the CS close to the RA orifice or, rarely, enters directly into the RA. At its junction with the CS, the venous entrance is occasionally much dilated, forming a venous diverticulum. CS venography is typically required to help delineate its anatomy and guide ablation.^{77,78}

The ideal ablation site is located within the branch of the CS containing the CS myocardial extension (coronary vein or neck of a CS diverticulum), at the site recording the largest, sharpest CS myocardial extension potential (similar to a BT activation potential) on the unipolar electrogram recorded from the ablation electrode. Typically, an irrigated-tip ablation catheter is used to allow more consistent delivery of RF energy, with less heating at the electrode-tissue interface. Standard RF energy delivery is often limited because of impedance or temperature rise (due to limited cooling from surrounding blood flow). Irrigated RF energy output of 10 to 20 W is initially delivered at sites within the CS, with the ablation catheter tip directed toward the ventricle within the CS (by maintaining a gentle counterclockwise torque on the ablation catheter).

Importantly, in some patients, branches of the distal right coronary artery (posterolateral branch) or left circumflex artery (posterior descending artery) course between the vein and the ventricle, just below the CS, adjacent to the ideal ablation site. RF ablation in close proximity to a coronary artery is associated with a high risk of arterial injury and should be avoided. Therefore once the ablation catheter is positioned at the target site, and before RF energy delivery, coronary arteriography is performed to outline the spatial relationship between the target vein and the adjacent coronary artery. Although the minimal safe distance between ablation sites and coronary arteries is not clear, the risk is highest for distances less than 2 mm and is negligible for distances more than 5 mm. Coronary arteriography is also performed after ablation to rule out damage to coronary arteries.⁸⁰

When close proximity of a coronary artery (within 2 to 4 mm) prohibits RF ablation, cryoablation offers a safe and reasonably effective alternative (albeit less effective than RF ablation).⁸¹ Freezing seems less likely to damage adjacent coronary arteries. Cryoablation may also be considered because it is not limited by high impedance and is likely facilitated by low blood flow. However, the cryocatheter can be difficult to maneuver in the coronary venous system.⁸⁰

The coronary venous approach can also be useful for mapping and ablation of left-sided AV BTs around the mitral valve and those traversing the inferior pyramidal space, the inferior BTs. Nevertheless, BTs located very close to the hinge of the mitral valve can be difficult to ablate because the CS is some distance away. Rarely, a transcutaneous pericardial approach is required to ablate epicardial BTs that are posteroseptal or right-sided. The success of this approach, however, remains limited, likely due to the anatomy of the AV groove, the thick epicardial fat layer covering the region where BTs are located, as well as the close proximity to the epicardial coronary arteries.^{77,78}

Causes of Failed Bypass Tract Ablation

Technical difficulties are the most common cause of failed BT ablation. These difficulties are typically related to catheter manipulation and stability (eFig. 18.9) or inability to access the target site. Catheter instability can lead to poor tissue contact and insufficient tissue heating at the optimal target site. These challenges are more common with right-sided BTs because of the smooth atrial aspect of the tricuspid annulus. Such difficulties can be overcome by using preformed guiding sheaths to help stabilize the catheter, using different catheter curvatures and shaft stiffness, changing the approach for ablation (e.g., from transseptal to transaortic, or from IVC to SVC), or changing the ablation modality. Also, cryoablation can help achieve better catheter stability and target sites that might otherwise be avoided because of the risk of damage to neighboring structures. Large (8-mm) ablation electrodes and cooled

eFig. 18.9 Poor Choice of Ablation Sites Because of Unstable Recordings. In the distal ablation bipolar (Abl_{dist}) recording, the atrial and ventricular electrograms have constantly changing amplitudes, signifying unstable electrode contact with tissue. Ablation should not be performed until the recordings are stable. Abl_{prox} , Ablation proximal bipolar electrodes; Abl_{uni} , ablation distal unipolar electrode; CS_{dist} , distal coronary sinus; CS_{prox} , proximal coronary sinus; His_{dist} , distal His bundle; His_{mid} , middle His bundle; His_{prox} , proximal His bundle; HRA , high right atrium; RVA , right ventricular apex.

RF ablation can also help generate large RF lesions; however, other causes of ablation failure should be considered first before shifting to those approaches, which are only rarely required for BT ablation because the target tissue (BT) is generally a thin strand, ablation of which should not require a large amount of tissue damage.

Mapping errors are the second most common cause of ablation failure. Mapping pitfalls are largely related to inaccurate localization of a BT that has an oblique course. This is more likely to occur when retrograde atrial activation mapping is performed with the ablation catheter positioned at the ventricular side of the annulus; because of the oblique course of the BT, the site of earliest atrial activation recorded from the ventricular aspect of the annulus does not correspond to the ventricular insertion site. Similar situations can occur when the ablation catheter is positioned on the atrial aspect of the annulus and RF applications are delivered where the earliest ventricular activation is recorded. In these situations, mapping for the earliest atrial activation site with the catheter on the atrial side of the annulus, or mapping for the earliest ventricular activation site with the catheter on the ventricular side of the annulus, should be undertaken.

Failure to recognize that a posteroseptal BT is left-sided rather than right-sided, and epicardial location of a left-sided or a posteroseptal BT, are other potential causes of failed ablation of those BTs. Detailed mapping in the CS should be considered in such situations. Furthermore, some BTs insert in the ventricle at a distance from the annulus, in which case a search for a presumed BT potential within the ventricle adjacent to the region of the earliest ventricular activation recorded at the annulus can be helpful. Unusual BTs (e.g., atriofascicular BTs) and anatomical abnormality (e.g., congenital heart disease) also account for some failures in BT ablation.

Failure to recognize the existence of multiple pathways can result in apparent failure of ablation of the target BT or recurrent tachycardia. Subtle changes in delta wave morphology during ablation of the target BT can help recognize the presence of more than one manifest BT. Furthermore, the use of a multielectrode EP catheter around the mitral annulus (via the CS) or tricuspid annulus (Halo catheter) can help recognize changes in retrograde atrial activation sequence or local VA timing during ablation of the target BT, which can be indicative of the presence of a second BT. In addition, concealed septal or para-septal BTs can be missed after ablation of a free-wall BT. Programmed ventricular and HB stimulation is important to avoid tachycardia recurrence.

Catheter-induced trauma to the BT also can lead to ablation failure (eFig. 18.10). Mechanical injury to the BT often persists for some time, leading to discontinuation of the mapping and ablation procedure in many cases, and the long-term risk for recovery of BT function is high. Superoparaseptal and atriofascicular BTs exhibit the highest susceptibility to mechanical trauma, followed by left free-wall BTs. The outcome can still be improved in these situations by close observation of the ECG recordings to recognize catheter-induced trauma of a BT promptly and, whenever conduction block in the BT does not resolve within 1 minute, by immediate application of RF energy, provided that the catheter has not moved from the site of presumed trauma. The location of the catheter tip when mechanical trauma occurred can be logged on electroanatomic mapping systems; some of these allow the user to “play back” where the catheter was seconds before the trauma occurred (if there is a question as to whether it has moved from that location). In addition, adenosine (likely due to its hyperpolarizing effects on atrial and BT tissues) can potentially transiently revive conduction through the injured BT secondary to mechanical trauma or partially successful ablation. This can help facilitate intermittent mapping during the transient adenosine effect.⁸² Finally, pace mapping the annulus to replicate the delta wave morphology can help guide ablation.

Outcome

RF ablation is a highly effective and curative treatment for AVRT, with acute success rates greater than 95%. Acutely successful RF ablation is usually persistent and late recurrence of BT conduction after ablation is rare (4%). Short runs of palpitations after ablation are frequent, are usually caused by isolated or short runs of PACs or PVCs and not by recurrence of BT conduction, and can be easily managed with symptomatic treatment. When BT-mediated tachycardia does recur, symptoms are usually observed during the first month after ablation; on the other hand, later onset of symptoms (more than 3 months after the ablation) are highly suggestive of SVTs not related to the ablated BT and justify a thorough evaluation (e.g., event monitoring, long-term ECG monitoring, new EP study).

In a survey of 6065 patients, the long-term success rate was 98% and a repeat procedure was necessary in 2.2% of cases. Serious complications (e.g., cardiac tamponade, AV block, coronary artery injury, retroperitoneal hemorrhage, stroke) occurred in 0.6% of patients, with one fatality (0.02%). Thus the one-time risk of catheter ablation appears to be considerably lower than the cumulative annual risk associated with the WPW syndrome. Hence, catheter ablation remains the treatment of choice for patients with the WPW syndrome who may be at risk for life-threatening arrhythmias. In addition, the highly favorable risk-benefit ratio justifies the use of catheter ablation as first-line therapy for any patient with BT-dependent tachycardia requiring treatment.

Success rates and risk of complications vary with different BT locations. Acute and long-term success rates are highest for left free-wall BTs. The immediate success rate of transaortic ablation of left free-wall BTs is 86% to 100% (highest with anterograde BT activation), and the recurrence rate is 2% to 5%, less frequent than for BTs at other locations. Complications of this approach include vascular complications (50% of all complications: groin hematoma, aortic dissection, and thrombosis), cardiac tamponade, stroke, coronary dissection (from direct catheter trauma), injury to the left circumflex coronary artery (from subannular RF application), valvular damage, and systemic embolism (from aortic atherosclerosis, catheter tip coagulum, or ablation site thrombosis). The transseptal approach, on the other hand, is associated with a success rate of 85% to 100%, a recurrence rate of 3% to 6.6%, and a complication rate of 0% to 6%. Such complications include coronary spasm, cardiac tamponade, systemic embolization (0.08%), and death (0.08%).

As compared with other BT locations, ablation of right free-wall BT is associated with the lowest acute success rate (88%), and highest recurrence rate (21%), but a low complication rate. On the other hand, ablation of posteroseptal BTs is associated with higher success rates (up to 98%) and a recurrence rate of 12%. For superoparaseptal BT ablation, the reported success rate is up to 97%, with a risk of RBBB in 5% to 10% of cases. Similarly, ablation of midseptal BTs is associated with a success rate of 98%, with an incidence of first-degree AV block in 2% and second-degree AV block in 2%. Although with superoparaseptal BT ablation RF energy is frequently applied at locations with visible His potential, the risk of high-grade AV block is higher for ablation of midseptal BTs because the compact AVN is located in the midseptum. In contrast to the well-insulated HB, the compact AVN is fragile and more vulnerable to damage during ablation.^{62,76}

The ablation of epicardial BTs (within the CS) is associated with a success rate of 62% to 100% and a complication rate of 0% to 6%. Complications associated with this approach include CS spasm, cardiac tamponade, pericarditis, and right coronary artery spasm or occlusion. The overall incidence of coronary artery injury is low (0.1%) and it can present immediately or several weeks after ablation.⁸³

A working definition of an atypical bypass tract (BT) is a conduction pathway that bypasses all or part of the normal conduction system but is not a rapidly conducting pathway connecting atrium and ventricle near the mitral or tricuspid annulus. Thus pathways that connect the atrium to the His bundle (HB) (atrio-Hisian BT), the atrioventricular node (AVN) to the His-Purkinje system (HPS) (nodofascicular BT), or the ventricle (nodovertricular BT), or the HPS to the ventricle (fasciculoventricular BT) fit into this designation (Fig. 19.1).

“MAHAIM FIBERS”

In 1937, during pathological examination of the heart, Mahaim and Benatt identified islands of conducting tissue extending from the HB into the ventricular myocardium. These fibers were called *Mahaim fibers* or *fasciculoventricular fibers*. This description was subsequently expanded to include connections between the AVN and the ventricular myocardium (nodovertricular fibers). Later, it was recognized that BTs could arise from the AVN and insert into the right bundle branch (RB) (nodofascicular fibers). This classification for Mahaim fibers persisted until evidence suggested that the anatomical substrate of tachycardias with characteristics previously attributed to nodovertricular and nodofascicular fibers is actually atrioventricular (AV) and atriofascicular BTs with decremental conduction properties (i.e., conduction slows at faster heart rates) (Fig. 19.1). Although these BTs are sometimes collectively referred to as “Mahaim fibers,” the use of this term is discouraged because it is more illuminating to name the precise BT according to its connections. In this chapter, these BTs are collectively referred to as *atypical* BTs to differentiate them from the more common (*typical*) rapidly conducting AV BTs, which insert into ventricular myocardium near the AV annulus and result in the Wolff-Parkinson-White (WPW) syndrome, or concealed BTs.¹

“MAHAIM TACHYCARDIA”

The term *Mahaim tachycardia* is used to describe the typical constellation of electrophysiological (EP) features that characterize the unusual form of reentrant tachycardia using an atypical BT without implying the underlying anatomical cause. It should be noted that, because the term was originally applied to an anatomical finding and subsequently (incorrectly) applied to physiology that matched what would be expected from this anatomy, it has given rise to more confusion than understanding. Hence use of the term *Mahaim tachycardia* should generally be discouraged; instead, one should simply describe the physiological characteristics of the tachyarrhythmia.

ATYPICAL ATRIOVENTRICULAR AND ATRIOFASCICULAR BYPASS TRACTS

Long Decrementally Conducting Atrioventricular and Atriofascicular Bypass Tracts

Atriofascicular and long AV BTs constitute the majority (80%) of atypical BTs. These BTs predominantly arise from the right atrium (RA) free wall; cross the tricuspid annulus in the lateral, anterolateral, or anterior region; extend along the right ventricular (RV) free wall to the region where the moderator band usually inserts at the apical third of the RV free wall; and insert into the distal part of the RB (atriofascicular BT) or into the ventricular myocardium close to the RB (long decrementally conducting AV BT). These BTs are functionally similar to the normal AV junction, with an AVN-like structure leading to an HB-like structure. In essence, these BTs function as an auxiliary conduction system parallel to the normal conduction system (AVN-HPS). Similar to the normal AVN, these BTs demonstrate decremental conduction (related to the

Fig. 19.1 Types of Bypass Tracts (BTs). The right atrium and ventricle are depicted. 1, Atriofascicular BT; 2, long atrioventricular BT; 3, nodo-fascicular BT; 4, nodovenous BT; 5, fasciculoventricular BT; 6, atrio-Hisian BT; 7, typical short atrioventricular BT. AV node, Atrioventricular node.

slow rate of recovery of excitability) and Wenckebach-type block in response to rapid atrial pacing and are sensitive to adenosine. The conduction delay in these BTs has been localized to the intraatrial portion of the BT (the AVN-like portion), whereas the interval from the inscription of the BT potential at the tricuspid annulus and the onset of ventricular activation (BT-V interval) remains constant.²⁻⁴ These BTs are typically unidirectional, conducting only in the anterograde direction; retrograde conduction block in the BT occurs near the atrial insertion.

Short Decrementally Conducting Atrioventricular Bypass Tracts

These BTs are analogous to the decrementally conducting concealed BTs responsible for permanent junctional reciprocating tachycardia (PJRT) (see Chapter 18) in that they bridge the AV rings and insert proximally into ventricular myocardium in close proximity to the AV annulus. These BTs primarily arise from the RA free wall but can also arise from the posterior or septal region. Left-sided BTs with decremental conduction characteristics have rarely been described. These BTs demonstrate prolonged conduction time over their length (more than 30 milliseconds) and decremental conduction and Wenckebach-type block in response to rapid atrial pacing. However, they do not consistently appear to be responsive to adenosine, which suggests that their structure is not composed of AVN-like tissue. Similar to atriofascicular BTs, short AV BTs conduct only anterogradely.⁵

An acquired form of short AV decrementally conducting BTs has been reported to be caused by incomplete radiofrequency (RF) ablation of typical rapidly conducting AV BTs. These BTs are capable of being part of an arrhythmia circuit. The decrease in conduction velocity may potentially be related to a decrease in cell-to-cell coupling caused by RF ablation-mediated injury.⁶

Arrhythmias Associated With Atypical Atrioventricular and Atriofascicular Bypass Tracts

Atypical AV and atriofascicular BTs in patients with clinical arrhythmias have the following characteristics: (1) unidirectional (anterograde-only) conduction (with rare exceptions); (2) long conduction times; and (3) decremental conduction (i.e., cycle length [CL]-dependent slowing of conduction).

Atypical BTs constitute 3% to 5% of all BTs. The incidence is slightly higher (6%) in patients presenting with supraventricular tachycardia (SVT) with left bundle branch block (LBBB) morphology. Multiple BTs occur in 10% of patients with atypical BTs. In some cases, ventricular preexcitation over a rapidly conducting AV BT can mask the presence of an atypical BT, which becomes apparent only after ablation of the typical BT. Dual AVN pathways or multiple BTs occur in 40% of patients with atypical BTs. Atypical BTs can also be associated with Ebstein anomaly.

Supraventricular Tachycardias Requiring a Bypass Tract for Initiation and Maintenance

Antidromic atrioventricular reentrant tachycardia (AVRT) can use the atypical AV and atriofascicular BT anterogradely and the HPS-AVN retrogradely. Preexcited AVRT can also use the atypical BT anterogradely and a second AV BT retrogradely. In the latter case, the AVN can participate as an innocent bystander mediating anterograde or retrograde fusion.

Because these atypical BTs almost always conduct anterogradely only, they cannot mediate orthodromic AVRT but can mediate antidromic AVRT or can be innocent bystanders during other SVTs (e.g., atrioventricular nodal reentrant tachycardia [AVNRT]). However, they can coexist with typical rapidly conducting AV BTs. Right-free-wall atriofascicular BTs capable of both anterograde and retrograde conduction that participate in both antidromic and orthodromic AVRT have rarely been reported.

Supraventricular Tachycardias Not Requiring a Bypass Tract for Initiation and Maintenance

AVNRT, atrial tachycardia (AT), atrial flutter (AFL), or atrial fibrillation (AF) can coexist with atypical BTs, in which case the atypical AV and atriofascicular BTs function as bystanders, wholly or partly responsible for ventricular activation during the tachycardia. Of note, the overall incidence of AF in patients with atypical BTs is low (less than 2%); it is much lower than in those with the classic WPW syndrome. AVNRT is observed in less than 10% of patients with atypical BT-related tachycardia.¹

Electrocardiographic Features

Normal Sinus Rhythm

During normal sinus rhythm (NSR), the electrocardiogram (ECG) shows a normal QRS or minimal preexcitation in most patients with atypical BTs. Subtle preexcitation can be suspected by the absence of the normal septal forces (small q waves) in leads I, aVL, V₅, and V₆ and the presence of an rS complex in lead III in the setting of a narrow QRS. The degree of preexcitation depends on the relative conduction time over the AVN and BT. Maneuvers that prolong conduction over the AVN (e.g., atrial pacing, vagal maneuvers, or drugs) to a greater degree than prolongation of BT conduction will increase the degree of preexcitation.

Because atypical AV and atriofascicular BTs exhibit decremental conduction, increasing the atrial pacing rate results in prolongation of the P-delta interval. This is in contrast to the setting with typical rapidly conducting AV BTs, during which progressively faster atrial pacing rates result in increasing delay in AVN conduction, an increasing degree of

ventricular preexcitation, and a relatively fixed P-delta interval. The P-delta interval remains constant regardless of the degree of preexcitation because conduction over the typical BT displays less decrement than does the AVN.

Preexcited QRS Morphology

For atriofascicular BTs, the preexcited QRS is relatively narrow (133 ± 10 milliseconds); its morphology is classic for typical LBBB with a QRS axis between 0 and -75 degrees and a late precordial R/S transition zone (at lead V_4 or V_5 and sometimes V_6). A monophasic R wave, in lead I and rS pattern in lead V_1 are typically observed. The delta wave, classically seen with BTs inserting into the myocardium near the annuli, is characteristically absent. However, for long decrementally conducting AV BTs, the QRS is relatively wider (166 ± 26 milliseconds) and the LBBB pattern is less typical (with broad initial R in lead V_1). The QRS is even wider and the LBBB pattern is less typical with decrementally conducting short AV BTs than that with atriofascicular or long decrementally conducting AV BTs.⁷

Supraventricular Tachycardias

Arrhythmias associated with atypical BTs exhibit LBBB morphology and, most often in the setting of long decrementally conducting AV and atriofascicular BTs, left axis deviation on the surface ECG (Fig. 19.2). Several ECG features suggest (although are not diagnostic of) atypical BTs as the cause of an SVT with LBBB pattern, including (1) QRS axis between 0 and -75 degrees, (2) QRS duration of 150 milliseconds or less, (3) R wave in lead I, (4) rS complex in lead V_1 , and (5) precordial R wave transition in lead V_4 or later.

Electrophysiological Testing

Baseline Observations During Sinus Rhythm

In the baseline state, minimal or no preexcitation is present; thus the His bundle–ventricular (HV) interval is normal or slightly short.

Programmed atrial stimulation during sinus rhythm. Progressively shorter atrial pacing cycle lengths (PCLs) or atrial extrastimulation (AES) coupling intervals produce decremental conduction in both the atypical BT and, to a greater degree, the AVN (Fig. 19.3). Consequently, the atrial–His bundle (AH) interval increases, the QRS morphology gradually shifts to a more preexcited LBBB morphology, and the AV (A-delta) interval increases. However, the AV (A-delta) interval increases to a lesser degree than the AH interval. This is in contrast to the setting of typical rapidly conducting AV BTs whereby the AV (A-delta) interval remains constant despite prolongation of the AH interval and exaggeration of the degree of preexcitation, because the A-delta interval represents the constant, nondecremental conduction time over the typical AV BT.

With progressively shorter atrial PCLs or AES coupling intervals, the HV interval decreases as the His potential becomes progressively inscribed into the preexcited QRS (usually within the first 5 to 25 milliseconds after the onset of the QRS). The His potential eventually becomes activated retrogradely as the wavefront travels anterogradely down the BT and then retrogradely up the RB to the HB (Fig. 19.3). When the His potential is lost within the QRS, it is unclear whether anterograde AV conduction continues to propagate over the HB or block has occurred.

At the point of maximal preexcitation, the AV (A-delta) interval continues to prolong with more rapid pacing because of the decremental conduction properties of the BT, but the His-QRS relationship remains unaltered because the HB is activated retrogradely until block in the BT occurs. The fixed VH interval, despite shorter PCLs or AES coupling intervals, suggests that the BT inserts into or near the distal RB at the anterior free wall of the RV with retrograde conduction to the HB.

Whenever the VH interval is less than 20 milliseconds, insertion into the RB (i.e., atriofascicular or nodofascicular BT) is likely. On the other hand, with long decrementally conducting AV BTs, which insert into the ventricular myocardium close to the RB, the VH interval approximates the HV interval minus the duration of the His potential (because the His potential is activated retrogradely).

For short decrementally conducting BTs, the HB is activated anterogradely, and retrograde conduction to the HB is only seen following AV block or during antidromic AVRT. Decremental conduction (progressive prolongation of the AV interval) and Wenckebach-type block can develop in the BT. The conduction delay in these BTs is localized to the intraatrial portion of the BT; the interval from the inscription of the BT potential at the tricuspid annulus to the onset of ventricular activation (BT-V interval) remains constant.

Dual AVN physiology is common in patients with atypical BTs. Sometimes during AES, a jump from the fast to the slow AVN pathway prolongs the AH interval to a degree sufficient to unmask preexcitation over the BT, at which time the His potential becomes inscribed within the QRS.

The site of the earliest ventricular activation during preexcitation is at the RV apex for long, decrementally conducting AV BTs and atriofascicular BTs, but it is adjacent to the annulus near the base of the RV for short, decrementally conducting AV BTs (Fig. 19.4).

The site of atrial stimulation does not influence the degree of preexcitation in the setting of nodofascicular and nodoventricular BTs. Contrariwise, preexcitation becomes more prominent when atrial stimulation is performed closer to the atrial insertion site of AV or atriofascicular BTs.

Programmed ventricular stimulation during sinus rhythm. Because these BTs rarely have retrograde conduction, ventriculoatrial (VA) conduction during ventricular pacing is mediated solely by the HPS-AVN with a concentric atrial activation sequence and decremental properties in response to progressively shorter ventricular PCLs or ventricular extrastimulation (VES) coupling intervals. If rapid and fixed VA conduction is present, a separate retrogradely and rapidly conducting AV BT should be excluded.

Response to physiological and pharmacological maneuvers. Atriofascicular and long AV BTs are usually sensitive to autonomic changes and to adenosine, similar to the AVN. Adenosine produces conduction delay or block in most atypical BTs except for short decrementally conducting AV BTs (eFigs. 19.1 and 19.2). The conduction delay is localized to the intraatrial portion of the BT (i.e., between atrial and BT electrograms); the interval from the inscription of the BT potential at the tricuspid annulus and the onset of ventricular activation remains constant (analogous to adenosine effects of the AH and HV intervals of the normal AVN-HPS). When adenosine administration slows AVN conduction, an increase in the degree of preexcitation is noted in all types of BTs (as long as adenosine does not block the BT).

Induction of Tachycardia

Initiation by programmed atrial stimulation. Initiation of antidromic AVRT by an AES requires the following: (1) intact anterograde conduction over the BT, (2) anterograde block in the AVN or HPS, and (3) intact retrograde conduction over the HPS-AVN once the AVN resumes excitability following partial anterograde penetration. Whereas the latter is usually the limiting factor for the initiation of antidromic AVRT using typical rapidly conducting AV BTs, it is readily available in the setting of atypical BTs. This is because of the slow decremental conduction anterogradely over the atypical BT, providing adequate delay for full recovery of the HPS-AVN.

As noted, progressively shorter atrial PCLs (especially from the RA) result in progressive AV (A-delta) interval prolongation and a greater

eFig. 19.1 Adenosine-Sensitive Posterior Septal Atrioventricular (AV) Bypass Tract. Adenosine was administered by rapid injection 5 seconds before the beginning of the recording, made during ventricular pacing (S). Dashed red lines denote onset of retrograde atrial activation. After the first two stimuli, activation appears earliest in the His recordings (AV nodal, *green arrow*), but on the third and fourth complexes, the AV node is blocked and conduction is over a septal pathway (*blue arrow*). However, after this, there is complete retrograde block with high-to-low sinus atrial complexes. CS, Coronary sinus catheter; HRA, high right atrial catheter.

eFig. 19.2 Adenosine Transiently Blocks a Slowly Conducting Right Lateral Atrioventricular Bypass Tract. Adenosine is administered as shown during atrial pacing; preexcitation gradually decreases then transiently disappears (*green arrow*), returning consistently toward the end of the recording. Antidromic AVRT

B

Fig. 19.2 Atriofascicular Bypass Tracts (BTs). (A) Normal sinus rhythm (NSR) with no evidence of preexcitation. (B) Antidromic atrioventricular reentrant tachycardia (AVRT) using an atriofascicular BT. QRS morphology during tachycardia resembles left bundle branch block aberration because of anterograde activation over the atriofascicular BT. Retrograde P waves can be seen after the end of the QRS.

degree of preexcitation until it is maximal. Often, once maximal preexcitation has been achieved, cessation of pacing is followed by preexcited SVT. Progressively shorter AES coupling intervals similarly result in progressive AV (A-delta) interval prolongation and a greater degree of preexcitation until it is maximal. When anterograde AVN conduction fails but conduction persists over the BT, the HPS-AVN can be activated retrogradely to initiate antidromic AVRT.

The sudden appearance of preexcitation associated with a “jump” from the fast to the slow AVN pathway with a His potential inscribed

before ventricular activation or with a VH interval of less than 10 milliseconds strongly favors AVNRT. Although a slowly conducting atriofascicular BT that becomes manifest with a jump to the slow AVN pathway cannot be excluded, a consistent pattern of dual pathway dependence and an HV relationship too short to be retrograde from the distal RB would be unlikely. Induction of AVNRT with AES is almost always associated with a dual pathway response, which may not be seen if the impulse conducts anterogradely over the BT and captures the HB before it is activated by the impulse traversing the slow AVN pathway

Fig. 19.3 Effect of Atrial Extrastimulation (AES) on Preexcitation Via a Long Atrioventricular (AV) Bypass Tract (BT). No preexcitation is observed during normal sinus rhythm and during the pacing drive at a cycle length of 600 milliseconds (normal PR and His bundle–ventricular [HV] intervals). (A) AES produces decremental conduction in the atrioventricular node (AVN) with prolongation of the atrial–His bundle (AH) interval (from 60 to 100 milliseconds), associated with manifest preexcitation and shortening of the HV interval (from 49 to 22 milliseconds). (B and C) Progressively shorter AES coupling intervals produce decremental conduction in the BT and, to a greater degree, in the AVN. Consequently, the AH interval prolongs, the QRS morphology gradually shifts to a more preexcited left bundle branch block morphology, and the AV (P-delta) interval prolongs. However, the P-delta interval prolongs to a lesser degree than the AH interval. The HV interval decreases (becomes negative) but remains fixed (B and C), although the P-delta interval continues to prolong with more premature AES because of decremental conduction over the BT. The fixed ventricular–His bundle (VH) interval, despite shorter AES coupling intervals, suggests that the BT inserts into or near the distal right bundle branch (RB) at the anterior free wall of the right ventricle, with retrograde conduction to the His bundle (HB). However, because the VH interval is modestly long (40 milliseconds), a long decrementally conducting AV BT inserting into the ventricle close to the RB is more likely than an atriofascicular BT. (C) AV reentrant echo complex (red arrows) secondary to anterograde conduction over the BT and retrograde conduction over the AVN. HRA, High right atrial catheter.

anterogradely. In other cases, a jump can be seen, so that the anterograde His potential follows the QRS with a typical AVN echo to initiate SVT, analogous to 1:2 conduction initiating antidromic AVRT.

Initiation by programmed ventricular stimulation. Initiation of antidromic AVRT by ventricular pacing or VES requires the following: (1) retrograde block in the BT, which is almost always available, because the atypical BTs are usually unidirectional (anterograde only); (2) retrograde conduction over the HPS–AVN; and (3) adequate VA delay to allow for recovery of the atrium and BT so it can support subsequent anterograde conduction.

Ventricular pacing can initiate SVT in 85% of cases. Initiation is almost always associated with retrograde conduction up a relatively fast AVN pathway, followed by anterograde conduction down a slow pathway, which is associated with preexcitation. The anterograde slow pathway can be a BT (i.e., antidromic AVRT) or a slow AVN pathway (i.e., AVNRT with an innocent bystander BT). During induction of the SVT by ventricular pacing at a CL similar to the tachycardia cycle

length (TCL) or by a VES that advances the His potential by a coupling interval similar to the H–H interval during the SVT, the His bundle–atrial (HA) interval following the ventricular stimulus is compared with that during the SVT. An HA interval that is longer with ventricular pacing or VES initiating the SVT than that during the SVT suggests AVNRT. This occurs despite the fact that the H1–H2 interval of the VES (i.e., the interval between the His potential activated anterogradely by the last sinus beat to the His potential activated retrogradely by the VES initiating the SVT) exceeds the H–H interval during the SVT. Because the AVN usually exhibits greater decremental conduction with repetitive engagement of impulses than in response to a single impulse at a similar coupling interval, the more prolonged the HA with the initiating ventricular stimulus, the more likely the SVT is AVNRT. If the SVT uses the BT for anterograde conduction, the HA interval during ventricular pacing or the VES initiating the SVT, at a comparable coupling interval as the TCL, should have the same HA interval as during the SVT.

Fig. 19.4 Comparison of Atrioventricular and Atriofascicular Pathway Characteristics. Dashed red lines denote onset of preexcited QRS complexes. (A) Right anterolateral atrioventricular pathway. Note earliest ventricular activation during preexcitation at the lateral tricuspid annulus ("Halo 9-10," blue arrow, also noted on ablation [Abl] recordings), whereas the right ventricular apical (RVA) recording is much later. (B) Atriofascicular pathway; three complexes of atrial pacing (S) from the lateral tricuspid annulus are shown, with anterograde His potentials (H) on the first two (which show increasing degrees of preexcitation), then retrograde on the third (H'), since this complex is fully preexcited. Note that the earliest ventricular activation is now at the RVA, where a right bundle potential is seen (green arrow); ventricular activation at the annulus is later. An atriofascicular pathway potential is noted in the ablation recording (red arrow) from the annulus, but the local ventricular recording there follows the RVA recording.

Features of Tachycardia

Antidromic AVRT

Site of earliest ventricular activation. In the setting of atriofascicular, nodofascicular, and long decrementally conducting AV BTs, the earliest ventricular activation occurs at or near the RV apex. In contrast, for nodoventricular and short decrementally conducting AV BTs, the earliest ventricular activation occurs adjacent to the tricuspid annulus.

VH interval. For atriofascicular and nodofascicular BTs, the VH interval is short (16 ± 5 milliseconds), much shorter than the nonpreexcited HV interval and also shorter than the VH interval during ventricular pacing, because the BT inserts into the RB; hence the HB and ventricle are activated in parallel during antidromic AVRT but in sequence during ventricular pacing. Conduction time to the distal RB is short ($V\text{-RB} = 3 \pm 5$ milliseconds). For long decrementally conducting AV BTs, the VH interval is short (37 ± 9 milliseconds) but longer than that of atriofascicular BTs because the ventricle and HB are activated in sequence, not in parallel. In this setting, the VH interval approximates the HV interval minus the duration of the His potential because the BT inserts close to the RB and the His potential is activated retrogradely.

In the presence of long decrementally conducting AV BTs, conduction time to the distal RB ($V\text{-RB} = 25 \pm 6$ milliseconds) is longer than that for atriofascicular BTs. During antidromic AVRT using a nodoventricular or a short decrementally conducting AV BT, intermediate VH intervals are observed whereby the His potential is inscribed within the QRS. The VH interval during the AVRT is longer than the nonpreexcited HV interval as well as the VH interval during RV apical pacing, exceeding it by the time it takes the impulse to travel from the ventricular insertion site of the BT at the RV base to the distal RB (i.e., because of the long V-RB interval). When antidromic AVRT occurs in the presence of retrograde right bundle branch block (RBBB), the VH interval is long (the His potential is inscribed after the QRS and the VH interval is longer than the nonpreexcited HV interval). Retrograde block over the RB results in anterograde conduction over the distal RB (in the setting of atriofascicular BTs) or RV and transeptal impulse propagation with subsequent retrograde conduction over the left bundle branch (LB) into the HB and AVN. This results in an antidromic AVRT with a macroreentrant circuit incorporating the LB retrogradely and either an atriofascicular, a long decrementally conducting, or a short decrementally conducting AV BT anterogradely.

Atrioventricular relationship. For atriofascicular BTs, long decrementally conducting AV BTs, and short decrementally conducting AV BTs, a 1:1 A-V relationship is a prerequisite for the maintenance of antidromic AVRT, because parts of both the RA and the RV are critical components of the reentrant circuit. The AV interval is often more than 150 milliseconds due to the decremental conduction properties of the BT. However, in the setting of nodofascicular and nodoventricular BTs, the atrium is neither part of nor required for the reentrant circuit, and VA block or AV dissociation can (although rarely) be present without disrupting the SVT.

Response to drugs. These SVTs are very responsive to and are terminated easily with adenosine, calcium channel blockers, and beta-blockers.

Changes in TCL. Changes in the rate of antidromic AVRT using an atriofascicular or a long AV BT as the anterograde limb of the circuit can occur secondary to changes in the VA conduction time due to either retrograde RBBB or shift of retrograde conduction over a fast AVN pathway to conduction over a slow AVN pathway. Prolongation of the TCL reflects prolongation of the VH interval in the former setting but prolongation of the HA interval in the latter setting. In addition, VA conduction over the HB-AVN axis changing into VA conduction over a second BT can alter the TCL. When this occurs the change in the TCL will depend on the location of the ventricular insertion site of the second BT and the conduction properties of that BT. Therefore there can be a shortening or a prolongation of the TCL. The behavior of the V-RB and VH intervals in that situation will depend on where the block is located in the RB-HB-AVN axis.⁸

Response to RBBB. The development of RBBB (e.g., secondary to catheter-induced mechanical trauma or VES) during antidromic

AVRT increases the size of the reentrant circuit because the impulse cannot reach the HB through the RB, and it has to travel transeptally and then retrogradely over the LB. This results in prolongation in the VA interval and delay in the timing of the next atrial activation and, as a result, prolongation of the TCL. The increment in the VA interval occurs because of prolongation of the VH interval, while the HA interval remains constant.⁹

Diagnostic Maneuvers During Tachycardia

Programmed atrial stimulation during tachycardia

Resetting. To prove the presence of a BT and its participation in the SVT, a late-coupled AES is delivered from the lateral RA (close to the BT) when the AV junctional portion of the atrium is refractory (as indicated by the lack of advancement of local atrial activation in the HB or coronary sinus ostium [CS os] recording), so that the AES does not penetrate the AVN. This maneuver is analogous to the introduction of VES when the HB is refractory during orthodromic AVRT. If this AES resets (advances or delays) the timing of the next ventricular activation, it indicates that an anterogradely conducting AV or atriofascicular BT is present, and excludes nodoventricular and nodofascicular BTs. If the AES advances (or delays) the timing of the next ventricular activation and the advanced (or delayed) QRS morphology is identical to that during the SVT, this proves that the AV or atriofascicular BT also mediates preexcitation during the SVT, either as an integral part of the SVT circuit or as an innocent bystander (i.e., preexcited AVNRT). On the other hand, if the AES advances the timing of both the next ventricular activation and subsequent atrial activation, it proves that the SVT is an antidromic AVRT using an AV or atriofascicular BT anterogradely and excludes preexcited AVNRT (Fig. 19.5). Advancement of

Fig. 19.5 Atrial Extrastimulation (AES) During Antidromic Atrioventricular Reentrant Tachycardia (AVRT) Using an Atriofascicular Bypass Tract. A late-coupled AES (S2) delivered from the right atrium (RA) when the AV junctional atrium is refractory (as evidenced by the failure of the AES to affect the timing of atrial activation recorded by the proximal His bundle and proximal coronary sinus electrodes) results in a delay in the timing of the next QRS ("postexcitation") as well as a delay in the timing of the following atrial activation. This confirms the diagnosis of antidromic AVRT and excludes preexcited atrioventricular nodal reentrant tachycardia and ventricular tachycardia as potential mechanisms of this wide QRS complex tachycardia. CS_{dist}, Distal coronary sinus catheter; CS_{prox}, proximal coronary sinus catheter; His_{dist}, distal His bundle; His_{prox}, proximal His bundle; HRA, high right atrial catheter; RVA, right ventricular apical.

both ventricular and atrial activation by such an AES requires anterograde conduction over the BT followed by retrograde conduction over the AVN. This can occur during antidromic AVRT but not in AVNRT because, in the setting of AVNRT, the HB would be refractory owing to anterograde activation by the time the advanced ventricular impulse invades the HPS retrogradely, with subsequent failure of the advanced ventricular activation to penetrate the HPS-AVN and affect the timing of subsequent atrial activation.⁹

Entrainment. During entrainment of the SVT by atrial pacing at a PCL slightly shorter than the TCL, the presence of a fixed short VH interval suggests antidromic AVRT but does not exclude AVNRT. Atrial pacing can usually terminate the SVT, whereby anterograde block is always produced in the AVN with or without block in the BT. A short-coupled AES can block in the BT, terminating the SVT (in the setting of antidromic AVRT) or changing the SVT to a narrow QRS complex SVT at the same CL and same HA interval (in the setting of preexcited AVNRT).

Programmed ventricular stimulation during tachycardia. Introduction of a VES during the SVT that results in RBBB can be of diagnostic value. During AVNRT, such RBBB will not change the time of the next atrial activation because the ventricle and HPS are not parts of the AVNRT circuit. Conversely, during antidromic AVRT, retrograde block in the RB increases the size of the reentrant circuit and, as a result, prolongs the VH and VA intervals as well as the TCL.

Ventricular pacing can usually terminate the SVT. Termination occurs by retrograde invasion and concealment in the BT, resulting in anterograde block over the BT following conduction to the atrium through the AVN.

Differential Diagnosis

The goal of programmed electrical stimulation during SVT is evaluation of the relationships between the His potential, the QRS, and the VH interval during atrial pacing and during SVT and differentiation between the different types of atypical BTs (Box 19.1 and Fig. 19.6). In addition, exclusion of a separate BT is necessary, especially if a rapid and fixed VA interval exists during incremental rate ventricular pacing. Furthermore, it is important to differentiate between antidromic AVRT using the BT anterogradely and preexcited AVNRT, in which the BT is a bystander (Box 19.2).¹⁰

Mapping

Mapping principles for typical AV BTs—searching for sites with the earliest atrial activation during retrograde BT conduction and earliest ventricular activation during anterograde BT conduction—are largely inapplicable in the case of atypical BTs because of their unusual course and conduction properties. Therefore different approaches are employed.

Mapping of the ventricular insertion site of atriofascicular and long decrementally conducting AV BTs is difficult because of the long intra-cardiac course and distal insertion of these BTs, which shows extensive arborization over a wide area of ventricular muscle with a diameter of up to 0.5 to 2 cm. A propensity to temporary loss of conduction of the atypical BT because of catheter trauma further complicates ventricular mapping.

Since the majority of atypical BTs conduct anterogradely only, mapping of the atrial insertion site can be challenging but can be performed by (1) P-delta interval mapping by stimulation at different atrial

Fig. 19.6 Diagnostic Algorithm for Various Patterns of Preexcitation. AF, Atriofascicular; AV, atrioventricular; BT, bypass tract; FV, fasciculoventricular; NF, nodofascicular; NV, nodoventricular. (From Ali H, Sorgente A, Lupo P, et al. Nodo- and fasciculoventricular pathways: electrophysiological features and a proposed diagnostic algorithm for preexcitation variants. *Heart Rhythm*. 2015;12:1677–1682.)

BOX 19.1 Differentiation Among Different Types of Atypical BTs**Preexcited QRS Morphology**

- Atriofascicular BTs: The QRS is relatively narrow (133 ± 10 msec) and is classic for typical LBBB morphology.
- Long decrementally conducting AV BTs: The QRS is wider (166 ± 26 msec) and the LBBB pattern is less typical (with broad initial R in V1) than that with atriofascicular BTs.
- Nodofascicular BTs: Same as for atriofascicular BTs.
- Nodoverricular BTs: The QRS is significantly wider and the LBBB pattern is less typical than that with atriofascicular or long decrementally conducting AV BTs.
- Short decrementally conducting AV BTs: The QRS is significantly wider and the LBBB pattern is less typical than that with atriofascicular or long decrementally conducting AV BTs.

Site of Earliest Ventricular Activation

- Atriofascicular BTs: The earliest ventricular activation occurs at or near the RV apex.
- Long decrementally conducting AV BTs: The earliest ventricular activation occurs at or near the RV apex.
- Nodofascicular BTs: The earliest ventricular activation occurs at or near the RV apex.
- Nodoverricular BTs: The earliest ventricular activation occurs adjacent to the tricuspid annulus.
- Short decrementally conducting AV BTs: The earliest ventricular activation occurs adjacent to the tricuspid annulus.

Influence of Site of Atrial Stimulation

- Atriofascicular BTs: Preexcitation increases when atrial stimulation is performed closer to the atrial insertion site.
- Long decrementally conducting AV BTs: Preexcitation increases when atrial stimulation is performed closer to the atrial insertion site.
- Nodofascicular BTs: The degree of preexcitation is not influenced by the site of atrial stimulation.
- Nodoverricular BTs: The degree of preexcitation is not influenced by the site of atrial stimulation.
- Short decrementally conducting AV BTs: Preexcitation increases when atrial stimulation is performed closer to the atrial insertion site.

AES Delivered From Lateral RA During Antidromic AVRT When AV Junctional Atrium Is Refractory

- Atriofascicular BTs: The AES can advance or delay the next ventricular activation.

- Long decrementally conducting AV BTs: The AES can advance or delay the next ventricular activation.
- Nodofascicular BTs: The AES cannot advance the next ventricular activation.
- Nodoverricular BTs: The AES cannot advance the next ventricular activation.
- Short decrementally conducting AV BTs: The AES can advance or delay the next ventricular activation.

VH Interval During Maximal Preexcitation or Antidromic AVRT

- Atriofascicular BTs: The VH interval is short (VH interval = 16 ± 5 msec and V-RB interval = 3 ± 5 msec; VH interval < HV interval and < VH interval during RV pacing).
- Long decrementally conducting AV BTs: The VH interval is short but longer than that with atriofascicular BTs (VH interval = 37 ± 9 msec and V-RB interval = 25 ± 6 msec).
- Nodofascicular BTs: The VH interval is short, as for atriofascicular BTs.
- Nodoverricular BTs: The VH interval is intermediate (His potential is inscribed in the QRS, VH interval \geq HV interval; VH interval > HV interval and > VH interval during RV pacing).
- Short decrementally conducting AV BTs: The VH interval is intermediate, as for nodoverricular BTs.
- Antidromic AVRT in presence of retrograde RBBB: The VH interval is long (His potential is inscribed after the QRS, VH interval > HV interval).

Presence of VA Block or AV Dissociation

- VA block or AV dissociation during the SVT excludes atriofascicular, short decrementally conducting AV BTs, and long decrementally conducting AV BTs but does not exclude nodofascicular and nodoverricular BTs.

Effects of Adenosine

- Adenosine produces conduction delay in most atypical BTs (except for short decrementally conducting BTs).
- When adenosine administration slows AVN conduction but not the BT, an increase in the degree of preexcitation is noted in all types of BTs except for fasciculoventricular BTs, whereby the degrees of preexcitation and HV interval remain fixed.

sites, (2) recording of the BT potential at the tricuspid annulus, and (3) AES from the RA during antidromic AVRT.⁴

Careful mapping of the tricuspid annulus and the anterior free wall of the RV typically demonstrates discrete potentials with complexes comparable to those recorded at the AV junction. The BT potential is analogous to the His potential. Atrial pacing, AES, and adenosine produce delays proximal to the BT potential with a constant BT potential to the QRS (BT–V) interval. Faster atrial pacing produces Wenckebach block proximal to the BT potential.

Mapping the Atrial Insertion Site

Mapping the shortest atrial stimulus to the delta (S–V) interval. The mapping catheter is advanced from site to site along the atrial

aspect of the tricuspid annulus while pacing from its distal tip. The resulting interval between the stimulus and the onset of the delta wave (S–V interval) should decrease progressively as the BT atrial insertion site is approached and increase as it is passed. Thus the atrial pacing site associated with the shortest S–V interval is the site closest to the BT atrial insertion site. It is essential that pacing at different sites be performed at a constant PCL to avoid rate-dependent conduction slowing in the BT as a reason for changing the S–V interval.

This method is rarely used because of several limitations: (1) a constant distance of the mapping-pacing catheter from the tricuspid annulus must be maintained to reduce the influence of the time spent traversing intervening atrial tissue; (2) catheter manipulation during pacing can result in initiation of tachycardia, which must then be

BOX 19.2 Differentiation Between Antidromic AVRT and Preexcited AVNRT Using an Atypical BT

SVT Induction

- Induction of the SVT by ventricular pacing at a CL similar to the TCL, or by a VES that advances the His potential by a coupling interval similar to the H-H interval during the SVT; the HA interval following such a ventricular stimulus is compared with that during the SVT:
- $HA_{VES} > HA_{SVT}$ is diagnostic of AVNRT and excludes antidromic AVRT.
- $HA_{VES} \leq HA_{SVT}$ is diagnostic of antidromic AVRT and excludes AVNRT.

Features of the SVT

- Positive HV interval or VH interval ≤ 10 msec (especially when HA interval is ≤ 50 msec) suggests AVNRT.
- Continuation of the SVT at the same TCL despite anterograde block in the BT (by extrastimuli, drugs, mechanical trauma caused by catheter manipulation, or ablation) is consistent with AVNRT and excludes antidromic AVRT.
- Termination of the SVT or prolongation of the VA (and VH) interval and TCL with transient RBBB (caused by mechanical trauma or introduction of VES) is consistent with antidromic AVRT and excludes AVNRT.

AES Delivered From Lateral RA When AV Junction Is Refractory

- If the AES advances the timing of both the following ventricular activation and the subsequent atrial activation, it proves that the SVT is an antidromic AVRT using an AV or atriofascicular BT anterogradely and excludes preexcited AVNRT.

Entrainment of the SVT With Atrial Pacing

- The presence of a fixed short VH interval during entrainment of the SVT with atrial pacing favors antidromic AVRT over AVNRT (but does not exclude AVNRT).

RV Apical Pacing During NSR

- RV apical pacing at the TCL is performed and the HA interval during RV apical pacing versus the HA interval during SVT are compared:
- $HA_{SVT} < HA_{\text{pacing}}$ is diagnostic of AVNRT and excludes antidromic AVRT.
- $HA_{SVT} \geq HA_{\text{pacing}}$ is diagnostic of antidromic AVRT and excludes AVNRT.

AES, Atrial extrastimulation; AV, atrioventricular; AVNRT, atrioventricular nodal reentrant tachycardia; AVRT, atrioventricular reentrant tachycardia; BT, bypass tract; CL, cycle length; HA, His bundle–atrial; HV, His bundle–ventricular; NSR, normal sinus rhythm; RA, right atrium; RBBB, right bundle branch block; RV, right ventricle; SVT, supraventricular tachycardia; VA, ventriculoatrial; VES, ventricular extrastimulation; VH, ventricular–His bundle.

terminated to continue mapping; (3) optimal sites can be overlooked if they cannot be consistently paced because of unstable catheter contact; and (4) this method cannot be applied in the setting of incessant tachycardia or when AF is present.

AES mapping during supraventricular tachycardias. The BT atrial insertion site is close to the site from which the longest coupled AES delivered during preexcited tachycardia advances the timing of the next ventricular activation. Alternatively, the BT atrial insertion site is close to the site from which the greatest amount of advancement of the next ventricular activation occurs when using a fixed AES coupling interval.

This method is rarely used because of several limitations: (1) it is time-consuming; (2) it cannot be used if the SVT is difficult to initiate,

is nonsustained, or is irregular (such that spontaneous changes in AV intervals confuse the assessment); (3) a constant distance of the mapping-pacing catheter from the tricuspid annulus must be maintained to reduce the influence of the time spent traversing intervening atrial tissue; and (4) optimal sites can be overlooked if they cannot be consistently paced because of unstable catheter contact.

Mapping the Ventricular Insertion Site

Mapping the distal fascicular insertion site (for atriofascicular BTs). The distal insertion site of atriofascicular BTs can be localized by careful mapping along the lateral RV wall toward the apex, seeking the earliest site of ventricular activation during anterograde BT conduction (Fig. 19.7). A distal RB recording is usually present at this site. This method can be used to map any rhythm during which consistent preexcitation is present (atrial pacing, AF, and preexcited SVT). However, seeking the distal insertion is less precise because a distal RB recording may be localized, but not the portion into which the atriofascicular fiber inserts. It is most useful if the course of the atriofascicular BT can be traced from the tricuspid annulus to its insertion into the RB. In addition, ablation at the distal site offers no advantage unless catheter stability is better at that location as opposed to the tricuspid annulus. If the RB is ablated rather than the BT, RBBB will result. This will not only fail to eliminate the BT function but can also facilitate induction and maintenance of the SVT by increasing the size of the reentry circuit. This may be the only usable method in the presence of intractable AF, in which annular BT potentials are not readily distinguished from fibrillatory atrial signals.⁴

Mapping the distal ventricular insertion site (for slowly conducting AV BTs). Mapping is performed in the same fashion as for typical rapidly conducting AV BTs—seeking the ventricular site with the earliest unipolar or bipolar ventricular electrogram recording. However, there is evidence that a variable degree of arborization of the distal insertion site occurs in some patients. This feature makes the ventricular insertion site a less attractive ablation target because of the potential of requiring ablation of a relatively large amount of ventricular myocardium to be effective.

Mapping the Bypass Tract Potential

Direct recording of the BT potential at the tricuspid annulus is the most precise and preferred method of localizing the atypical BT. Mapping is performed during preexcited rhythm (typically during RA pacing or preexcited SVT). The BT potential is usually a low-amplitude, high-frequency recording made at the tricuspid annulus (*Mahaim* or *M potential*), which resembles a His potential (Figs. 19.4 and 19.8). Only the annular and subannular portions of the BT have been successfully recorded; attempts to record potentials from the atrial portion (corresponding to nodal-like tissue) have been unsuccessful. Distinct atrial, BT, and ventricular potentials can be found near the BT atrial insertion along the tricuspid annulus. Local ventricular activation at this location is delayed, occurring after the QRS onset, since ventricular activation starts close to the RV apex.

However, recording of a BT potential along the tricuspid annulus may not be successful in up to 48% of cases. Furthermore, because of its low amplitude, the BT potential can be difficult to visualize during AF. In addition, this technique presents the risk of producing mechanical block in the BT. Nevertheless, this method is less time-consuming and more precise than the previous ones.

Mapping Sites of Mechanically Induced Loss of Preexcitation

Atypical BTs are particularly sensitive to mechanical trauma, and catheter manipulation along the tricuspid annulus during mapping of the BT

Fig. 19.7 Anatomical Course of the Atriofascicular Pathway. Two complexes of antidromic tachycardia using an atriofascicular pathway are shown (red dashed line denotes onset of QRS complex). Letters on electrogram lines correspond to locations shown in the fluoroscopic image at right. *Abl.*, Ablation catheter; *CS*, coronary sinus catheter; *His_{dist}*, distal His bundle; *His_{prox}*, proximal His bundle; *HRA*, high right atrial catheter; *RBB*, right bundle branch; *RV*, right ventricular catheter.

Fig. 19.8 Ablation of an Atriofascicular Bypass Tract (BT). A discrete potential (arrows) is shown in the ablation recording during atrial pacing, with a small His potential occurring just after the onset of the pre-excited QRS. Ablation at this site eliminated this BT in 2 seconds. *Abl_{dist}*, Distal ablation catheter; *Abl_{prox}*, proximal ablation catheter; *His_{dist}*, distal His bundle; *His_{prox}*, proximal His bundle; *HRA*, high right atrial catheter; *RVA*, right ventricular apical.

can result in loss of BT function, even as a result of gentle pressure from the catheter tip. Atriofascicular BTs are more susceptible to mechanically induced block, probably suggesting that these BTs are composed of thinner strands or are located closer to the endocardium. When mapping is performed during preexcited atrial pacing or SVT, damage to the BT is indicated by a sudden loss of preexcitation or SVT termination. This phenomenon can be used to localize the BT precisely (“bump mapping”). Conduction block typically occurs while a BT potential is still recorded; thus conduction is interrupted within the ventricular course of the BT. Block usually lasts from a few beats to a few minutes but can last for hours, after which preexcitation resumes. This method can be used during any consistently preexcited rhythm (atrial pacing, AF, and antidromic AVRT). However, if it occurs during antidromic AVRT, termination of the tachycardia can result in catheter displacement and loss of the exact location of the BT. In addition, interruption of BT conduction can occur as the catheter is moving past the area, and where the catheter comes to rest may not be the same site as where loss of BT function occurred; in this situation, the target cannot be relocated until BT conduction resumes.

Delivery of RF energy at a site at which catheter pressure caused loss of preexcitation may successfully eliminate conduction in the BT; however, it is best to wait to deliver energy until preexcitation resumes because of the possibility that the catheter position may have changed. Electroanatomic mapping systems can help tag sites of interest, facilitating precise relocation of the ablation catheter to these sites if it has been determined that these are good ablation targets.

Adenosine (likely due its hyperpolarizing effects on atrial and BT tissues) can transiently restore conduction through the injured BT secondary to mechanical trauma or partially successful ablation. This can facilitate intermittent mapping during the transient adenosine effect but can require repeated drug administration.¹¹

Ablation

Target of Ablation

For atriofascicular and long AV BTs, direct recording of the BT potential at the tricuspid annulus is the most precise and preferred method of localizing the BT and serves as the target of ablation (Fig. 19.8). A three-component electrogram, including an atrial component, a BT (M) potential and a ventricular component, can frequently be identified near the BT atrial insertion along the tricuspid annulus. The local AV interval is usually longer than the surface VA interval because ventricular activation starts close to the RV apex, so that the local ventricular activation at the annular portion of the BT occurs after QRS onset. A specific BT potential can be recorded in about two-thirds of cases, typically along the right lateral, posterolateral, and anterolateral tricuspid annulus.

When a BT potential along the tricuspid annulus cannot be recorded, ablation of the proximal (atrial) or distal (ventricular) insertion sites of atriofascicular BTs becomes an alternative. Those approaches, however, are complex and less successful; they also often require time-consuming mapping (as discussed previously) and a larger number of RF lesions. Ablation at the ventricular insertion site of the BT offers no advantage over targeting the atrial insertion site because there is evidence that a variable degree of arborization of the distal insertion site occurs in some patients, with the potential of requiring ablation of a relatively large amount of ventricular myocardium to be effective. In addition, ablation of the ventricular insertion site is commonly (57%) associated with the development of RBBB. Ablation of the RB can carry a proarrhythmic effect and facilitate induction of the SVT or cause incessant tachycardia; however, this is not a concern as long as the BT itself is also successfully ablated.⁴

Catheter ablation of the AVN fast pathway, serving as the retrograde route of antidromic AVRT, had been reported as a therapeutic alternative. This, however, is associated with a significant risk of complete AV block and is not recommended.¹²

Ablation Technique

Once an appropriate target site for ablation has been identified, RF energy may be applied during NSR, atrial pacing, or antidromic AVRT. Atrial pacing is preferred to ensure that adequate preexcitation is evident (unlike NSR) to be able to assess the efficacy of ablation, and that the rhythm remains the same after elimination of preexcitation (unlike antidromic AVRT) to prevent catheter dislodgment.⁴

The use of long preshaped or steerable sheaths can help achieve good catheter positioning and stability along the tricuspid annulus. Typical RF settings consist of a maximal power of 50 W and a maximal temperature of 55°C to 60°C, continued for 30 to 60 seconds after elimination of the BT function (i.e., after disappearance of preexcitation). During RF energy delivery, an accelerated preexcited rhythm is often observed. This so-called *Mahaim automatic tachycardia* is analogous to the accelerated junctional rhythm observed during AVN modification and is presumably secondary to heating-related automaticity of nodal-like tissue of the BT. Accelerated automatic beats during RF ablation have been considered a marker of a successful result and should not be misinterpreted as an inaccurate location but rather should prompt continuation of RF energy delivery for a sufficient duration after termination of this rhythm. Heat-induced automaticity during RF ablation is observed less commonly in short, decrementally conducting AV BTs as compared with atriofascicular BTs (50% vs. 91%).

A recent report found cryoablation to be a reliable and effective alternative to RF ablation in the treatment of atriofascicular BTs in children.¹³

Endpoints of Ablation

Complete loss of BT function, not just noninducibility of tachycardias, is an essential endpoint. BT block is confirmed by demonstrating loss of preexcitation with atrial pacing and AES and noninducibility of AVRT. Atrial stimulation should be performed at sites and rates that were associated with preexcitation before ablation.

Outcome

The acute success rates for ablation of atriofascicular BTs range between 68% and 90%, with long-term recurrence rates of about 10% and 15%.¹²

NODOFASCICULAR AND NODOVENTRICULAR BYPASS TRACTS

Nodoventricular/nodofascicular BTs arise in the normal AVN and insert into ventricular myocardium near the para-Hisian region (nodoventricular) or into the RB (nodofascicular). The hallmark of nodofascicular/nodoventricular BTs is their infra-atrial nature. Unlike other atypical BTs, nodofascicular/nodoventricular BTs can exhibit anterograde-only, bidirectional, or retrograde-only (concealed) conduction (Box 19.1 and Fig. 19.6).¹⁴

Arrhythmias Associated With Nodofascicular and Nodoventricular Bypass Tracts

Nodoventricular or nodofascicular BTs can participate as the retrograde limb of orthodromic AVRT (“nodofascicular reentrant tachycardia”). However, only rare reports have implicated these BTs as the anterograde limb of antidromic AVRT unless another AV BT (rather than the HB) serves as the retrograde limb.¹⁵

Electrocardiographic Features

Nodofascicular/nodoventricular BTs commonly present with minimal preexcitation. During ventricular preexcitation mediated via manifest nodofascicular BTs, the QRS is relatively narrow (133 ± 10 milliseconds), and its morphology is classic for typical LBBB with a QRS axis between 0 and -75 degrees and a late precordial R/S transition zone at lead V_4 or beyond (similar to atriofascicular BTs). A monophasic R wave, in lead I and rS pattern in lead V_1 are typically observed. The QRS is wider and the LBBB pattern is less typical with nodoventricular BTs than that with nodofascicular BTs.⁷

Electrophysiological Testing

Baseline Observations During Sinus Rhythm

Nodofascicular/nodoventricular BTs are not totally infranodal, but they bypass only a portion of the AVN with decremental conduction properties. Consequently, the atrial impulse has to propagate through the proximal portion of the AVN, which underlies the “decremental” conduction properties of these BTs and their exquisite “AVN-like” sensitivity to isoproterenol and adenosine. Therefore only minimal preexcitation is usually apparent during NSR. In addition, atrial stimulation with progressively shorter PCL or AES coupling intervals causes progressive prolongation of the atrial stimulus-delta (S-delta) interval. As a result, the degree of preexcitation can change and the HV interval can decrease even to negative values. This phenomenon usually necessitates a significant AH prolongation to dissociate the anterograde conduction over the nodofascicular/nodoventricular BT and the distal portion of the AVN and consequently to change the degree fusion and preexcitation. The more proximal the emergence level of the BT from the AVN, the more evident this feature, and vice versa.¹⁶

Characteristically, the site of atrial stimulation does not influence the degree of preexcitation in the setting of nodofascicular and nodoventricular BTs (similar to fasciculoventricular BTs). In contrast, preexcitation becomes more prominent when atrial stimulation is performed closer to the atrial insertion site of AV or atriofascicular BTs.

The presence of preexcited junctional beats (originating proximally, such as those during ablation of the slow AVN pathway) excludes AV and atriofascicular BTs and favors the diagnosis of an fasciculoventricular or nodofascicular/nodoventricular BT. Conversely, junctional beats originating from the proximal HB cause normalization of the HV interval and QRS morphology in the setting of nodofascicular/nodoventricular BTs but maintain an identical degree of preexcitation in the presence of a fasciculoventricular BT.¹⁶

Tachycardia Features

In the setting of orthodromic AVRT utilizing a nodofascicular or nodoventricular BT, both atrial and ventricular activation is mediated by the normal AVN-HPS. The QRS complex is narrow since the AVN-HPS forms the anterograde limb of the tachycardia circuit. Furthermore, retrograde activation is mediated initially by the BT, which then inserts within the AVN, and the upper turnaround point of the reentry circuit is subatrial. For atrial activation to occur, the tachycardia wavefront has to travel retrogradely over the upper portion of the AVN. Hence the earliest atrial activation occurs at the insertion of the AVN fast (or slow) pathway.

For nodofascicular and nodoventricular BTs, the atrium is neither part of nor required for the reentrant circuit, and VA block or AV dissociation can be present without disrupting the SVT. This is in contrast to AVRT utilizing AV or atriofascicular BTs, whereby a 1:1 AV relationship is critical for continuation of the tachycardia.

Diagnostic Maneuvers During Tachycardia

Nodofascicular reentrant tachycardia shares many features with orthodromic AVRT using an AV BT as the retrograde limb of the circuit, and

BOX 19.3 Differentiation Between Nodofascicular Reentrant Tachycardia and Orthodromic AVRT Using an AV BT

Diagnostic Maneuvers During NSR

- Progressive prolongation of the atrial stimulus-delta (S-delta) interval during atrial stimulation with progressively shorter PCL or AES coupling intervals is consistent with nodofascicular/nodoventricular BTs.
- The degree of ventricular preexcitation in the setting of nodofascicular and nodoventricular BTs is not influenced by the site of atrial stimulation. In contrast, preexcitation becomes more prominent when atrial stimulation is performed closer to the atrial insertion site of AV BTs.
- The presence of preexcited junctional beats excludes AV BTs and favors the diagnosis of an fasciculoventricular or nodofascicular/nodoventricular BT.

Diagnostic Maneuvers During SVT

- VA block or AV dissociation during the SVT suggests that nodofascicular and nodoventricular BTs exclude AV BTs.
- Dissociation of the atrium from the tachycardia during atrial pacing maneuvers suggests that nodofascicular and nodoventricular BTs exclude AV BTs.
- ΔAH interval ($AH_{\text{pacing}} - AH_{\text{SVT}}$) > 40 msec favors nodofascicular reentrant tachycardia.
- AVN/AVN response pattern during para-Hisian pacing favors a nodofascicular BT.
- Manifest ventricular fusion during RV apical pacing argues against a nodofascicular BT and favors nodoventricular and AV BTs.

AES, Atrial extrastimulation; AH, atrial–His bundle; AV, atrioventricular; AVN, atrioventricular node; AVRT, atrioventricular reentrant tachycardia; BT, bypass tract; HA, His bundle–atrial; NSR, normal sinus rhythm; PCL, pacing cycle length; RV, right ventricular; SVT, supraventricular tachycardia.

similar maneuvers are utilized to identify the presence of a retrogradely conducting BT and its participation in the reentrant circuit (see Boxes 18.3 and 18.4). However, a few differences exist, which are helpful in identifying the presence of a nodofascicular/nodoventricular BT (Box 19.3). Most importantly, the nodofascicular reentrant tachycardia circuit is completely subatrial; therefore the atrium can be dissociated from the tachycardia circuit by pacing maneuvers. In addition, because of the parallel activation of the atrium and HB during nodofascicular reentrant tachycardia (since the tachycardia circuit is subatrial), the AH interval during tachycardia is shorter than the AH interval during atrial pacing. In contrast, the AH interval during orthodromic AVRT utilizing an AV BT approximates that during atrial pacing, given similar sequential activation of the atrium and HB in both settings. As a result, the ΔAH interval ($AH_{\text{pacing}} - AH_{\text{SVT}}$) during nodofascicular reentrant tachycardia can be longer than 40 milliseconds, as occurs with AVNRT, but it is less than 40 milliseconds in orthodromic AVRT utilizing an AV BT. The ΔAH interval criterion is especially helpful to distinguish nodofascicular reentrant tachycardia from PJRT. Moreover, a nodofascicular BT can show an AVN/AVN response pattern with para-Hisian pacing, especially if it originates from the proximal branch of the RB. In such a case, the SA interval with direct HB-RB capture would be shorter than during pure myocardial capture where the RB is retrogradely activated.¹⁷

Of note, slow, decremental BT conduction can affect the sensitivity of the postpacing interval (PPI)–TCL, ΔVA and ΔHA criteria for orthodromic AVRT, although the specificity of these criteria remains high. Long PPIs are common and a [PPI–TCL] less than 125 milliseconds

seems better than a cutoff of 115 milliseconds for differentiating orthodromic AVRT (PJRT and nodofascicular reentrant tachycardia) from atypical AVNRT. In a recent report, any standard criterion positive for orthodromic AVRT ([PPI–TCL] < 115 milliseconds, corrected [PPI–TCL] < 110 ms, Δ VA < 85 milliseconds, and Δ HA < 0 milliseconds) was found to be diagnostic of orthodromic AVRT despite discordance between them, which occurred 50% of the time.¹⁷

Resetting of the SVT with a VES delivered when the HB is refractory can help to identify the presence of nodofascicular/nodoventricular BTs. Not infrequently, such a VES causes a delay in the next atrial activation in the setting of slow or decremental BT mediating retrograde conduction during SVT, which confirms the diagnosis of orthodromic AVRT (similar to PJRT). The degree of the delay depends on the relative prematurity of the VES compared with the degree of BT conduction delay.^{17,18}

Manifest ventricular fusion can be demonstrated during RV entrainment of orthodromic AVRT using a nodoventricular BT. However, in the setting of a nodofascicular BT, the tachycardia circuit is contained within the specialized conduction system; hence manifest ventricular fusion may not be demonstrable.¹⁷

Mapping

Mapping the BT potential at the midseptum has been reported, but a distinct BT potential is usually difficult to differentiate from the RB potential. Alternatively, the BT distal insertion can be mapped using VES or ventricular entrainment. The distal insertion site of the BT is identified as the site where maximum advancement of the His potential can be achieved with a single VES (with a fixed coupling interval) during orthodromic tachycardia or at the site where the shortest PPI (during concealed entrainment) occurs with the shortest stimulus-to-His (VH) interval can be demonstrated.

Ablation

For nodofascicular and nodoventricular BTs, ablation targets the site where the BT potential is recorded or, alternatively, the BT distal insertion site. The initial ablation target is typically located in the AVN slow pathway region (between the CS os and tricuspid annulus). Ablation in the midseptum or floor of the CS may be required.¹⁴ Importantly, RF ablation of nodofascicular/nodoventricular pathways is associated with an increased risk of AV block. Cryoablation offers significant safety advantage in these cases.

FASCICULOVENTRICULAR BYPASS TRACTS

General Considerations

Fasciculoventricular BTs are among the rarest forms of preexcitation (1.2% to 5.1% of atypical BTs). They connect the HB to ventricular myocardium in the anterosseptal location; this is likely due to a gap in, or absence of, the usually present fibrous sheath that insulates the HB from adjacent myocardium. These fibers do not give rise to any reentrant tachycardia and appear to be only an ECG and EP curiosity. Even during AF and AFL, a rapid ventricular response is not expected in the presence of a normal AVN proximal to the BT (Box 19.1 and Fig. 19.6). However, it is important to distinguish fasciculoventricular BTs from superoparaseptal AV BTs to avoid unnecessary invasive EP procedures and potential harm to the AVN–HB if such a BT is mistakenly targeted by ablation because this form of preexcitation does not require treatment.¹⁶

Of note, a rare form of familial fasciculoventricular BTs has been reported in association with mutations in the *PRKAG2* gene (which encodes the gamma-2 regulatory subunit of the adenosine monophosphate [AMP]–activated protein kinase). These patients have a high

incidence of syncope, cardiac arrest, ventricular hypertrophy, atrial arrhythmias, sinus bradycardia, and complete AV block; therefore they should be distinguished from those without structural heart disease.^{16,19}

Electrocardiographic Features

In patients with fasciculoventricular BTs, preexcitation is always present during NSR. The ECG preexcitation pattern can mimic that of manifest WPW pattern, especially that of superoparaseptal AV BTs, with a normal frontal plane axis between 0 and 75 degrees and precordial RS transitional zone in leads V₂–V₃. With fasciculoventricular BTs, the PR interval is normal despite the presence of preexcitation (Fig. 19.9). This is in contrast to superoparaseptal AV BTs, which result in the WPW pattern with significant shortening of the PR interval because of the relative proximity of the BT location to the sinus node.

Several ECG findings in lead V₁ favor fasciculoventricular BTs as the cause of preexcitation, including (1) a PR interval longer than 110 milliseconds, (2) R wave width less than 35 milliseconds, (3) S wave amplitude less than 20 mm, (4) a flat or negative delta wave, and (5) notching in the descending limb of the S wave (Fig. 19.9).

Electrophysiological Testing

Baseline Observations During Sinus Rhythm

With fasciculoventricular BTs, preexcitation is present during NSR with a normal AH interval and fixed and short but positive HV interval (usually greater than 10 milliseconds). The earliest ventricular activation occurs at the HB region (Box 19.4).

The presence of preexcited junctional beats excludes AV and atriofascicular BTs and favors the diagnosis of a fasciculoventricular BT. These junctional beats may occur spontaneously or be provoked by isoproterenol infusion, RF ablation of the slow pathway, or the pause induced after burst atrial pacing or adenosine administration. These beats are associated with the same degree of preexcitation and the same HV interval as during NSR (Fig. 19.10), even when these beats are associated with retrograde VA block and no atrial depolarization. However, junctional beats emerging proximally in the AV junction (e.g., during RF ablation of the AVN slow pathway) may produce preexcitation over fasciculoventricular BTs as well as nodofascicular/nodoventricular BTs. Conversely, junctional beats originating from the HB distal to the origin of the fasciculoventricular BT can cause normalization of the HV interval and QRS morphology.¹⁶

BOX 19.4 Features of Fasciculoventricular Bypass Tracts

- Preexcitation is present in NSR with a normal PR interval with a transitional zone in V₂–V₃.
- The earliest ventricular activation occurs at the HB region.
- The degree of preexcitation is not influenced by the site of atrial stimulation.
- Incremental rate atrial pacing results in progressive prolongation in the P-delta interval, but the degree of preexcitation is not influenced by the pacing rate.
- HB pacing does not change the degree of preexcitation or the HV interval.
- Junctional beats (even when associated with retrograde VA block) are associated with the same degree of preexcitation and the same HV interval as during NSR.

HB, His bundle; HV, His bundle–ventricular; NSR, normal sinus rhythm.

Programmed Atrial Stimulation

Progressively shorter atrial PCLs or AES coupling intervals produce progressive, physiological prolongation of the PR and AH intervals but with a fixed degree of preexcitation, a constant and positive (usually greater than 10 milliseconds) HV interval, and a fixed relationship between the HB and RB potentials (Fig. 19.11). AVN Wenckebach block can develop, which is then associated with a fixed degree of preexcitation and a constant, short HV interval. The loss of AV conduction is associated with loss of preexcitation.

AES can result in block in the fasciculoventricular BT, producing a sudden loss of preexcitation and prolongation of the HV interval to normal values (Fig. 19.11). Multisite atrial pacing has no effect on the preexcitation degree in fasciculoventricular BTs (similar to nodofascicular/nodoventricular BTs). This maneuver is helpful to differentiate these BTs from AV and atriofascicular BTs.

Programmed His Bundle Stimulation

HB pacing normalizes the HV interval and eliminates preexcitation in all types of BTs except for fasciculoventricular BTs, in which a fixed

Fig. 19.9 Electrocardiogram (ECG) of Fasciculoventricular Bypass Tracts. (A) Surface ECG of normal sinus rhythm (NSR) with preexcitation over a fasciculoventricular pathway. Note the short PR and slight slurring of the QRS upstroke in several leads. (B) Pacing from the right atrium (RA) at the shortest cycle length associated with 1:1 atrioventricular (AV) conduction results in no change in the mild degree of preexcitation compared with NSR despite atrioventricular nodal conduction delay (longer PR interval).

Continued

Fig. 19.9, cont'd (C) Atrial fibrillation (AF) is present, with no change in the mild degree of preexcitation compared with NSR regardless of the R-R interval. (D) Surface ECG during His bundle (HB) pacing in the same patient. The same degree of preexcitation persists as in NSR. Retrograde P waves are visible (arrows), deforming the end of QRS complexes.

degree of preexcitation and a constant short HV interval remain unchanged during HB pacing (Fig. 19.10).¹⁶

Response to Pharmacological Maneuvers

When adenosine administration slows AVN conduction, an increase in the degree of preexcitation is noted in all types of BTs as long as adenosine does not block the BT except for fasciculoventricular BTs, in which the degree of preexcitation and HV interval remain fixed.

ATRIO-HISIAN BYPASS TRACTS

General Considerations

Patients with palpitations who had a short PR interval but normal QRS complex in the resting ECG were first described in 1938 and then further evaluated by Lown and colleagues in 1952. The latter report consisted of a retrospective examination of 13,500 ECGs and identified short PR intervals in a mixed group of 200 subjects, most of whom had a normal

Fig. 19.10 Fasciculoventricular Bypass Tract. Full 12 leads of electrocardiogram are shown with intracardiac recordings during a junctional complex at left and a sinus complex with atrioventricular conduction at right. A dotted red line denotes QRS onset. Preexcitation is present in both QRS complexes to the same degree, indicative of a fasciculoventricular pathway. The His (*H*)-ventricular interval is short (28 milliseconds). CS, Coronary sinus catheter; *RVA*, right ventricular apical.

Fig. 19.11 Effect of Atrial Stimulation of Fasciculoventricular Bypass Tracts (BTs). (A) Minimal preexcitation is present during normal sinus rhythm, with the same during atrial pacing and following an atrial extra-stimulus (AES) that lengthens the atrial-His bundle interval, but the His bundle-ventricular (HV) interval remains fixed at only 20 milliseconds. These features are consistent with a fasciculoventricular pathway. (B) A more premature AES results in block in the fasciculoventricular pathway, resulting in a narrow QRS complex and normal HV interval (40 milliseconds). Note the difference in QRS complex morphology following the AESs (arrows). *His_{dist}*, Distal His bundle; *His_{prox}*, proximal His bundle; *HRA*, high right atrial catheter; *RVA*, right ventricular apical.

QRS complex (Fig. 19.12). The authors described a “syndrome” (“Lown-Ganong-Levine [LGL] syndrome”) characterized by short PR interval, narrow QRS complex, and recurrent paroxysmal SVTs. They initially ascribed this syndrome to the presence of an atrioventricular nodal BT. However, a variety of explanations were later offered to account for the short PR interval.

Although the incidence of palpitations was significantly higher in those patients with short PR intervals when compared with a control group with normal PR intervals (17% vs. 0.5%), most contemporary electrophysiologists do not consider the “LGL syndrome” to be a recognized syndrome consisting of a single entity but rather an electrocardiographic description. It probably represents one end of the normal spectrum of AVN conduction properties. Therefore use of the term

“LGL syndrome” is inappropriate and should be discouraged and the mechanism responsible for the short PR interval should be used instead. The persistence of the term probably relates to the appealing parallel with the initials of the WPW syndrome.²⁰

The short PR interval can have different mechanisms: (1) enhanced AVN conduction (perhaps using specialized intranodal fibers), which is believed responsible for most cases of short PR interval and is secondary to an anatomically small AVN, enhanced sympathetic tone, or a variant of normal; (2) atrio-Hisian BT (rare), in which case AF or AFL with a rapid ventricular response is the presenting arrhythmia (Table 19.1); (3) ectopic atrial rhythm with differential input into the AVN; and (4) isorhythmic AV dissociation, whereby the short PR interval is not caused by a conducted P wave.

An “enhanced AVN conduction” has been arbitrarily defined as (1) AVN conduction time (AH interval) less than 60 milliseconds during NSR, (2) 1:1 AV conduction at atrial PCLs less than 300 milliseconds, and (3) maximal increment in the AH interval of 100 milliseconds or less during pacing at a PCL of 300 milliseconds compared with the value measured during NSR.

Supraventricular Tachycardias in Patients With Short PR Intervals

Patients With Enhanced Atrioventricular Node Conduction

The mechanism(s) of SVTs in patients with enhanced AVN conduction does not appear to differ significantly from those in patients with normal PR intervals (AVNRT being the most common, followed by orthodromic AVRT). The TCL of AVNRT occurring in patients with short PR intervals is not different from that in patients with normal PR intervals. This is expected because the TCL of AVNRT is determined by conduction over the slow AVN pathway, which is similar in these patients and those with normal PR intervals. In contrast, the TCL of orthodromic AVRT tends to be much shorter in these patients than in patients with normal PR intervals, which is expected because the circuit of orthodromic AVRT uses the fast AVN pathway for anterograde conduction. In fact, in any SVT with a TCL shorter than 250 milliseconds, enhanced AVN conduction and orthodromic AVRT should be suspected. In such patients, bundle branch block (BBB) is common during SVT (to provide sufficient AV delay necessary to maintain reentry), resulting in wide complex tachycardia.²⁰

Patients With Atrio-Hisian Bypass Tracts

These patients primarily present with AF and AFL with a rapid ventricular response and do not develop reentrant SVTs using the AV junction as one limb. Rapid ventricular rates during AF depend on refractoriness of the tissue responsible for AV conduction (i.e., AVN or BT) and not on the site of insertion for that tissue.

Electrophysiological Testing

Baseline Observations During Sinus Rhythm

Enhanced AVN conduction is characterized by a short AH interval (less than 60 milliseconds) and normal HV interval. In rare cases in which the AVN is completely bypassed by an atrio-Hisian BT, the HV interval is short. The HV interval in these cases is artifactually short because the proximal HB and the ventricle are activated in parallel, since the atrio-Hisian BT inserts into the distal HB (i.e., the proximal HB is activated retrogradely).²⁰

Programmed Atrial Stimulation

Patients with enhanced AVN conduction. The AH interval prolongs with progressively shorter atrial PCLs and AES coupling intervals. The prolongation in the AH interval is smooth, continuous, and blunted, with a maximal increase in the AH interval of 100 milliseconds or less during pacing at a CL of 300 milliseconds compared with the value measured during NSR. The maximal AH interval (at any PCL) is rarely longer than 200 milliseconds and 1:1 conduction typically is maintained at PCLs shorter than 300 milliseconds.

The AH interval response can be characteristic of dual AVN physiology, with an initial blunted small prolongation in the AH interval followed by a significant jump at a critical PCL or AES coupling interval while maintaining 1:1 conduction at PCLs shorter than 300 milliseconds. In such patients, the maximal AH interval can be longer than 200 milliseconds, and the maximal prolongation in the AH interval can be greater than 100 milliseconds. Atrial pacing from the CS is associated with shorter AH intervals, shorter Wenckebach CLs, and shorter AVN effective refractory periods, suggesting a preferential input into the AVN.²⁰

Patients with atrio-Hisian BTs. The AH interval remains short with no or minimal prolongation in response to progressively shorter atrial PCLs and AES coupling intervals. Block in the BT, which can usually be achieved by antiarrhythmic agents or occasionally by the induction of AF, is associated with a simultaneous increase in the PR and AH intervals and normalization of the HV interval.²¹

Programmed Ventricular Stimulation

Patients with enhanced AVN conduction. Retrograde AVN conduction is extremely rapid in these patients. In general the HA interval is shorter than the AH interval at comparable PCLs. The HA interval typically remains relatively short with little prolongation in response to progressively shorter ventricular PCLs and VES coupling intervals. A concealed AV BT mediating retrograde VA conduction should be excluded, which can be achieved by a variety of pacing maneuvers (see Chapter 18).

Patients with atrio-Hisian BTs. VA conduction is unpredictable in these patients. In many cases VA conduction is absent and, even when present, is not as good as AV conduction.

Response to Pharmacological and Physiological Maneuvers

Patients with enhanced AVN conduction. The AH interval prolongs in response to beta-blockers, verapamil, digoxin, carotid sinus massage, and vagal maneuvers. Complete autonomic blockade results in increases in the AH interval and AVN functional refractory period but a minimal change in the AVN effective refractory period (suggesting sympathetic tone predominance in these patients, in contrast to individuals with normal AVN conduction in whom vagal tone predominates).

Patients with atrio-Hisian BTs. AV conduction over the atrio-Hisian BT is not affected by autonomic modulation. Conduction block in the BT requires class IA or IC agents or amiodarone. Conduction block is associated with an immediate, sudden, and marked prolongation of the AH and HV intervals to normal values.

A “supraventricular” origin of a tachycardia implies the obligatory involvement of one or more cardiac structures above the bifurcation of the His bundle (HB), including the atrial myocardium, atrioventricular node (AVN), proximal HB, coronary sinus (CS), pulmonary veins, venae cavae, or abnormal atrioventricular (AV) connections other than the HB (i.e., bypass tracts [BTs]).¹

Narrow QRS complex supraventricular tachycardia (SVT) is a tachyarrhythmia with a rate greater than 100 beats/min and a QRS duration of less than 120 milliseconds. Narrow complex SVTs include sinus tachycardia, inappropriate sinus tachycardia, sinoatrial nodal reentrant tachycardia, focal atrial tachycardia (AT), multifocal AT, atrial fibrillation (AF), atrial flutter (AFL), junctional tachycardia, atrioventricular nodal reentrant tachycardia (AVNRT), and atrioventricular reentrant tachycardia (AVRT). These tachycardias can be divided into those that require only atrial tissue for their initiation and maintenance (sinus tachycardia, AT, AF, and AFL), and those that require the AV junction (junctional tachycardia, AVNRT, and AVRT).

Paroxysmal SVT is the term generally applied to intermittent SVT other than AF, AFL, and multifocal AT, and describes a clinical syndrome characterized by the presence of a regular and rapid tachycardia of abrupt onset and termination (Fig. 20.1). The major causes are AVNRT (approximately 50% to 60% of cases), AVRT (approximately 30% of cases), and focal AT (approximately 10% of cases).

years. The risk of developing paroxysmal SVT is twofold greater in women than men.¹

In a large cohort of patients with symptomatic paroxysmal SVT referred for ablation, AVNRT was the most common mechanism (56%), followed by AVRT (27%) and AT (17%). However, the mechanism of paroxysmal SVT was significantly influenced by both age and gender. The majority of patients with AVRT are men (55%), whereas the majority of patients with AVNRT and AT are women (70% and 62%, respectively). As patients grew older, there was a significant and progressive decline in the number of patients presenting with AVRT, which was the predominant mechanism in the first decade, and a striking increase in AVNRT and AT (Fig. 20.2). These trends were similar in both genders, although AVNRT replaced AVRT as the predominant mechanism much earlier in women.²

AVNRT is the predominant mechanism overall in patients undergoing ablation, and after the age of 20 years it accounts for the largest number of ablations in each age group. AVNRT is unusual in children under 5 years of age, and typically initially manifests in early life, often in the teens. There is a striking 2:1 predominance of women in the AVNRT group, which remains without clear physiological or anatomical explanation. Female sex and older age (teens vs. early childhood years) favor the diagnosis of AVNRT over AVRT.³

AVRT presents earlier in life than AVNRT (most commonly in the first two decades of life), with an average of more than 10 years separating the time of clinical presentation of AVRT versus AVNRT. The early predominance of AVRT is consistent with the congenital nature of the substrate. However, a minority of patients have relatively late onset of symptoms associated with AVRT and thus continue to account for a small proportion of ablations in older patients. Men account for a higher proportion of AVRT at all ages.⁴

Focal ATs comprise a progressively greater proportion of paroxysmal SVT with increasing age, accounting for 23% of paroxysmal SVTs in

EPIDEMIOLOGY AND NATURAL HISTORY

Paroxysmal SVT with sudden onset and termination is relatively common. In the United States, the estimated prevalence in the general population is 2.29 per 1000, with an incidence of 36 per 100,000 person-years. Paroxysmal SVT in the absence of structural heart disease can present at any age but most commonly first presents between ages 12 and 30

patients older than 70 years. Although there is a greater absolute number of women with AT, the proportion of AT in both genders is similar. Age-related changes in the atrial electrophysiology (EP) substrate (including cellular coupling and autonomic influences) likely contribute to the increased incidence of AT in older individuals.² In adults, focal ATs can occur in the absence of structural heart disease; nonetheless, the

incidence of associated structural heart disease is higher in AT than other types of paroxysmal SVT.⁵ The long-term prognosis in patients with focal AT is generally benign, except for those with incessant ATs, which can precipitate tachycardia-induced cardiomyopathy.¹

Unlike AF and AFL, paroxysmal SVT does not appear to be a risk marker for stroke. In fact, unexplained stroke is rare in patients with SVT. Nonetheless, a strong link exists between SVT and atrial arrhythmias, particularly paroxysmal AF, even in patients with no ventricular preexcitation. The prevalence of a history of AF in the SVT patient population is approximately 2.6% compared to 0.4% to 2% in the general population. In addition, AVRT and, less frequently, AVNRT can serve as triggers for AF.⁶

CLINICAL PRESENTATION

The clinical syndrome of paroxysmal SVT is characterized as a regular rapid tachycardia of abrupt onset and termination. Episodes can last from seconds to several hours. Patients commonly describe palpitations and heart racing, frequently associated with complaints of dyspnea, weakness, chest pain, dizziness, or even frank syncope. The impact of SVT on quality of life varies according to the frequency and duration of episodes, and the severity of symptoms.¹ Patients often learn to use certain maneuvers such as carotid sinus massage or the Valsalva maneuver to terminate the arrhythmia, although many require pharmacological treatment to achieve this.

Neck pounding can occur during tachycardia, which is related to pulsatile reversed flow when the right atrium (RA) contracts against a closed tricuspid valve. The physical examination correlate of this phenomenon is continuous pulsing cannon A waves in the jugular venous waveform (described as the “frog” sign). This clinical feature has been reported to distinguish typical AVNRT from orthodromic AVRT. Although the atrial contraction during orthodromic AVRT does occur against closed AV valves, the longer ventriculoatrial (VA) interval during the tachycardia results in separate ventricular and then atrial contractions and, hence, relatively lower RA and venous pressures. Therefore symptoms of “shirt flapping” or “neck pounding” are experienced less commonly in patients with AVRT than those with AVNRT (17% vs. 50%). In addition, polyuria, which related to higher RA pressures and elevated levels of atrial natriuretic protein, is more common in patients with AVNRT compared with patients who have AVRT.¹

Dizziness can occur initially because of hypotension, but it then disappears when the sympathetic response to the SVT stabilizes the blood pressure (typically within 30 to 60 seconds). Reductions of blood pressure and cardiac output (and the associated reflex sympathetic activity) are likely to be most prominent in SVTs with simultaneous atrial and ventricular activation (e.g., typical AVNRT) than those with short VA intervals (e.g., slow-slow AVNRT or orthodromic AVRT), and least prominent in long RP tachycardias (e.g., atypical AVNRT, permanent junctional reciprocating tachycardia [PJRT], and AT).¹

True syncope is rare but can occur, especially in elderly patients. Syncope at the initiation of SVT is commonly vagally mediated, especially in young patients, and is benign in nature. However, malignant ventricular arrhythmias as a cause of syncope should be considered in patients with manifest preexcitation. In these patients, AVRT can deteriorate into AF, which can be associated with very fast ventricular rates, with possible degeneration into ventricular fibrillation (VF).

In patients with underlying structural heart disease, symptoms can be more severe. Decompensation of underlying heart failure or ischemic heart disease can be precipitated by episodes of SVT. Truly paroxysmal SVT rarely leads to a tachycardia-induced cardiomyopathy. However, PJRT and focal AT can manifest as a frequently recurring or incessant tachycardia that can precipitate cardiomyopathy and heart failure. Elimination of the tachycardia results in normalization of left ventricular (LV) function within a few months in the vast majority of patients.⁷

INITIAL EVALUATION

History, physical examination, and an electrocardiogram (ECG) constitute an appropriate initial evaluation of patients presenting with symptoms suggestive of paroxysmal SVT. However, clinical symptoms are not usually helpful in distinguishing different forms of paroxysmal SVT. A 12-lead ECG during tachycardia can be helpful for defining the mechanism of paroxysmal SVT. Ambulatory 24- or 48-hour Holter recording can be used for documentation of the arrhythmia in patients with frequent (i.e., several episodes per week) but self-terminating tachycardias. A cardiac event monitor is often more useful than a 24-hour recording in patients with less frequent arrhythmias. Implantable loop recorders can be helpful in selected cases with rare episodes associated with severe symptoms of hemodynamic instability (e.g., syncope).

An echocardiographic examination should be considered in patients with documented sustained SVT to exclude the possibility of structural heart disease. Exercise testing is rarely useful for diagnosis unless the arrhythmia is clearly triggered by exertion. Further diagnostic studies are indicated only if there are signs or symptoms that suggest structural heart disease. Of note, troponin I and T levels (especially high-sensitivity Troponin T) are elevated in a significant proportion (more than 50%)

of patients presenting with SVT, but this elevation does not constitute a clear biomarker of clinically significant coronary artery disease.⁸ Similarly, striking ST segment depression during SVT, that resolves quickly on cessation of tachycardia, is not uncommon but does not signify obstructive coronary artery disease.

Invasive EP testing is not indicated unless a decision to proceed with catheter ablation is undertaken. EP testing with subsequent catheter ablation may also be used for diagnosis and therapy in cases with a clear history of paroxysmal regular palpitations. It may also be considered in patients with preexcitation or disabling symptoms without ECG documentation of an arrhythmia.

PRINCIPLES OF MANAGEMENT

Acute Management

Most episodes of paroxysmal SVT require intact 1:1 AVN conduction for continuation and are therefore classified as AVN-dependent. AVN conduction and refractoriness can be modified by vagal maneuvers and by many pharmacological agents and thus are the weak links targeted by most acute therapies. Termination of a sustained episode of SVT is usually accomplished by producing a transient block in the AVN (Fig. 20.3).

Fig. 20.3 Ongoing Management of Supraventricular Tachycardia (SVT) of Unknown Mechanism. Drugs listed alphabetically. ^aClinical follow-up without treatment is also an option. EP, Electrophysiology; pt, patient; SHD, structural heart disease (including ischemic heart disease); SVT, supraventricular tachycardia. (From Page RL, Joglar JA, Caldwell MA, et al. 2015 ACC/AHA/HRS guideline for the management of adult patients with supraventricular tachycardia: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines and the Heart Rhythm Society. *J Am Coll Cardiol*. 2016;67:e27–e115.)

For acute conversion of SVT, vagal maneuvers (including Valsalva and carotid sinus massage) are the first-line intervention, although their success rate remains limited (less than 30%). Valsalva is the most effective technique in adults, but carotid sinus massage can also be effective. The so-called modified Valsalva (patient supine, with legs slightly elevated to increase venous return and decrease reflex sympathetic tone) has also been useful. Facial immersion in water is the most reliable method in infants. Vagal maneuvers are less effective once a sympathetic response to paroxysmal SVT has become established, so patients should be advised to try them soon after onset of symptoms.¹

When vagal maneuvers are unsuccessful, termination can be achieved with antiarrhythmic drugs whose primary effects increase AVN refractoriness or decrease AVN conduction. In most patients, the drug of choice is intravenous (IV) adenosine. In hemodynamically stable patients, IV diltiazem, verapamil, or beta-blockers are appropriate therapy for SVT that is refractory to adenosine or recurs after initial termination, and are successful in 64% to 98% of cases. Electrical cardioversion is recommended for acute treatment in patients with hemodynamically unstable SVT when vagal maneuvers or adenosine are ineffective or not feasible.¹

The advantages of adenosine include its rapid onset of action (usually within 10 to 25 seconds via a peripheral vein), short half-life (less than 10 seconds), and high degree of efficacy. The effective dose of adenosine is usually 6 to 12 mg, given as a rapid bolus over 1 to 2 seconds at a peripheral site, followed by a vigorous flush of normal saline. If a central IV access site is used, the initial dose should not exceed 3 mg and may be as little as 1 mg. Doses up to 12 mg terminate over 90% of paroxysmal SVT episodes (predominantly AVRT and AVNRT). Sequential dosing can be given at 60-second intervals because of adenosine's rapid metabolism. In AVNRT, termination is usually caused by block in the slow pathway. In AVRT, termination occurs secondary to block in the AVN. Termination can also occur indirectly, that is, because of adenosine-induced premature atrial complexes (PACs) or premature ventricular complexes (PVCs). Adenosine also can terminate a significant proportion of focal ATs; therefore termination of an SVT in response to adenosine is not helpful in differentiating AT from other SVTs. Even when AT persists, adenosine can be useful diagnostically by producing transient AV block and unmasking the independent atrial activity during AT. Of note, adenosine is cleared rapidly; hence, reinitiation of paroxysmal SVT after initial termination can occur. Either repeated administration of the same dose of adenosine or substitution of a calcium channel blocker or beta-blocker typically is effective.

Importantly, adenosine shortens the atrial refractory period, and atrial ectopy can induce AF. This can be dangerous if the patient has a BT capable of rapid anterograde conduction, which can result in a rapid ventricular response that can degenerate into VF. In patients with Wolff-Parkinson-White (WPW) syndrome and AF, adenosine can result in a rapid ventricular response that can degenerate into VF. However, this problem has not been observed frequently, and the use of adenosine for diagnosis and termination of regular SVTs, including AVRT, is appropriate as long as close patient observation and preparedness to treat potential complications, such as with immediate electrical cardioversion/defibrillation, are maintained.

The AVN action potential is calcium channel-dependent, and the non-dihydropyridine calcium channel blockers verapamil and diltiazem are effective for terminating AVN-dependent paroxysmal SVT. The recommended dosage of verapamil is 5 mg IV over 2 minutes, followed in 5 to 10 minutes by a second 5- to 7.5-mg dose. The recommended dose of diltiazem is 20 mg IV followed, if necessary, by a second dose of 25 to 35 mg. Paroxysmal SVT termination should occur within 5 minutes of the end of the infusion, and more than 90% of patients with AVN-dependent paroxysmal SVT respond. As with adenosine,

transient arrhythmias, including PACs, PVCs, AF, and bradycardia, can be seen after paroxysmal SVT termination with calcium channel blockers. Hypotension can also develop, particularly if the paroxysmal SVT does not terminate. Adenosine and verapamil have been reported to have a similar high efficacy in terminating paroxysmal SVT, with a rate of success ranging from 59% to 100% for adenosine and from 73% to 98.8% for verapamil, according to the dose and mode of administration. However, data also suggest that the efficacy of adenosine and verapamil is influenced by the arrhythmia rate. Adenosine appears to be more effective at terminating SVT with faster rates. In contrast, the efficacy of verapamil in restoring sinus rhythm was inversely related to the rate of paroxysmal SVT.

IV beta-blockers including propranolol (1 to 3 mg), metoprolol (5 mg), and esmolol (500 µg/kg over 1 minute and a 50-µg/kg per minute infusion) are also useful for acute termination. Digoxin (0.5 to 1.0 mg) is considered the least effective of the four categories of drugs available, but is a useful alternative when there is a contraindication to the other agents.

AVN-dependent paroxysmal SVT can present with a wide QRS complex in patients with fixed or functional aberration, or if a BT is used for anterograde conduction. Most wide complex tachycardias, however, are caused by mechanisms that can worsen after IV administration of beta-blockers and calcium channel blockers. Unless there is strong evidence that a wide QRS tachycardia is AVN-dependent, verapamil, diltiazem, and beta-blockers should not be used.
